ABSTRACT

Background: Anxiety disorders are associated with decreased heart rate variability (HRV), but the underlying mechanisms remain elusive.

Methods: We selected individuals with whole-genome sequencing, Fitbit, and electronic health record data (N=920; 61,333 data points) from the All of Us Research Program. Anxiety PRS were derived with PRS-CS after meta-analyzing anxiety genome-wide association studies from three major cohorts- UK Biobank, FinnGen, and the Million Veterans Program (N Total =364,550). The standard deviation of average RR intervals (SDANN) was calculated using five-minute average RR intervals over full 24-hour heart rate measurements. Antidepressant exposure was defined as an active antidepressant prescription at the time of the HRV measurement in the EHR. The associations of daily SDANN measurements with the anxiety PRS, antidepressant classes, and antidepressant substances were tested. Participants with lifetime diagnoses of cardiovascular disorders, diabetes mellitus, and major depression were excluded in sensitivity analyses. One-sample Mendelian randomization (MR) was employed to assess potential causal effect of anxiety on SDANN.

Results: Anxiety PRS was independently associated with reduced SDANN (beta=-0.08; p=0.003). Of the eight antidepressant medications and four classes tested, venlafaxine (beta=-0.12, p=0.002) and bupropion (beta=-0.071, p=0.01), tricyclic antidepressants (beta=-0.177, p=0.0008), selective serotonin reuptake inhibitors (beta=-0.069; p=0.0008) and serotonin and norepinephrine reuptake inhibitors (beta=-0.16; p=2x10⁻⁶) were associated with decreased SDANN. One-sample MR indicated an inverse effect of anxiety on SDANN (beta=-2.22, p=0.03).

Conclusions: Anxiety and antidepressants are independently associated with decreased HRV, and anxiety appears to exert a causal effect on HRV. Our observational findings provide novel insights into the impact of anxiety on HRV.

INTRODUCTION

Anxiety disorders are common mental illnesses that affect one out of five patients in a primary care setting(1). In addition to their psychiatric comorbidities, anxiety disorders are associated with multiple somatic diseases(2) consequently leading to increased overall morbidity and mortality(3). Anxiety disorders often co-occur with decreased heart rate variability (HRV)(4), which has been described as an independent predictor of all-cause mortality(5). Decreased HRV can reflect impaired autonomic control(6), a mechanism that has been proposed to contribute to the association of HRV with anxiety(7). Antidepressant medications may also play a role. However, the literature regarding the role of antidepressants in this relationship remains inconclusive, and, in some cases, contradictory(8). The effect of tricyclic antidepressants (TCAs) on HRV(9) has been proposed to account for the decreased HRV in anxiety disorders(10). Conversely, data on the effect of serotonin reuptake inhibitors (SSRIs) are conflicting, with studies showing both increased HRV, in the context of improved depressive symptoms(11), as well as decreased HRV(12). Other factors such as symptom severity and treatment response are likely to contribute to HRV relationship with anxiety and antidepressants.

Because of the multiple potential confounders, it is hard to dissect the underlying mechanisms of the association of anxiety with HRV in traditional observational studies. In recent years, large-scale genome-wide association studies (GWAS) identified a number of variants implicated in the genetic liability to anxiety disorders(13). Since genetic associations are less likely to be affected by reverse causation and other confounders(14), polygenic risk scores (PRS) and genetically informed causal inference analyses can be used to explore complex associations.

To understand the impact of anxiety on autonomic function it is important to measure HRV in real-life settings. Wearable devices are a valuable source of HRV data(15) and full 24-hour HRV metrics can capture circadian variation(16) and response to physical activity(17). In

particular, the standard deviation of average five-minute R-R intervals over 24 hours (SDANN) is strongly correlated with other HRV metrics(18) and has been found to be stable over time in the absence of major clinical events, like myocardial infarction(19).

In the present study, we leveraged genome-wide information on anxiety available from UK Biobank (UKB)(20), Million Veteran Program (MVP)(21), and FinnGen(22) and Fitbit data and electronic health records (EHR) from All of Us (AoU) Research Program(23) to investigate the association of anxiety and antidepressants with HRV, and we conducted sensitivity analyses to control for the effect of mental and physical comorbidities.

METHODS AND MATERIALS

Study Population

In this retrospective study, we used genetic information, EHRs, physical measurements, and wearable data from participants enrolled in the AoU Research Program(23). When enrolled in the AoU cohort, participants provided informed consent and consent for the release of EHR records separately. Our analyses were conducted from 02/2023 to 04/2023, using the sixth version of the AoU curated data repository (CDR), which was the most recent CDR version as of 02/2023. Age was extracted from AoU self-reported data and baseline body mass index (BMI) from AoU physical measurements. Genomic data were used to derive sex at birth, genetic ancestry, and the first 10 within-ancestry principal components (PCs). Details regarding the quality control of AoU whole-genome sequencing (WGS) data are reported in the **Methods** in **Supplement 1**.

Daily SDANN was calculated for AoU participants that had provided minute-level heart rate Fitbit measurements for at least one full day (1,440 minutes) in a Bring-Your-Own-Device model(24). Fitbit uses photoplethysmography to derive heart rate measurements(25)Data extraction and SDANN calculation were conducted using R (**Methods** in **Supplement 1**). Participants' health conditions were derived from EHR data that were previously

standardized using the Observational Medical Outcomes Partnership (OMOP) vocabulary and SNOMED codes(26). Specifically, we extracted phenotypic information regarding anxiety and conditions that could affect the anxiety-HRV association(27-30). These included myocardial infarction (MI), arrhythmias (Ar), congestive heart failure (CHF), diabetes mellitus (DM) as well as major depressive disorder (MDD). The primary EHR diagnostic subcategories for each phenotype are described in **Table S1**. We also extracted antidepressant prescriptions from EHR data for each date of SDANN measurement (**Table S2**) and assigned them to their respective antidepressant categories (**Table S3**). Our analyses considered antidepressant prescriptions with a start date earlier than the SDANN measurement date and a stop date later than the SDANN measurement date or missing. For our sensitivity analyses, we also accounted for lifetime exposure to beta blockers and calcium channel blockers.

Polygenic Risk Scoring of Anxiety

To maximize the statistical power of the anxiety PRS analysis, we combined genome-wide association statistics previously generated from three large biobanks: UKB(20), FinnGen(22), and MVP(21). For UKB, we used GWAS data from the Pan-UKB analysis (details at <https://pan.ukbb.broadinstitute.org/>). Briefly, the genome-wide association analysis was conducted using regression models available in Hail (available at <https://github.com/hail-is/hail>) and including the top-20 within-ancestry PC, sex, age, age², sex × age, and sex × age² as covariates. For the FinnGen GWAS, we used data from Release 8 (details at <https://finngen.gitbook.io/documentation/v/r8/>) which were generated with REGENIE(31) including age, sex, top-10 within-ancestry PCs, and genotyping batch as covariates. For both cohorts, we considered definitions of anxiety disorders based on EHR data. Phecode 300 “anxiety disorders” including 10,449 cases and 369,930 controls was used for the UKB GWAS. The FinnGen GWAS was conducted using the endpoint “anxiety disorders” (KRA_PSY_ANXIETY) including 35,385 cases and 254,976 controls. Regarding MVP, we investigated data generated from a previous GWAS of anxiety symptoms assessed

via the Generalized Anxiety Disorder (GAD) 2-item scale in 175,163 participants of European descent(32). To meta-analyze GWAS of binary and quantitative phenotypes, we used the sample-weighted approach available in METAL(33), using effective sample size ($N_{effective} = 4/(1/N_{cases} + 1/N_{controls})$) for the binary phenotypes. The meta-analysis was restricted to GWAS including individuals of European descent because of the limited sample size of other population groups.

Using the anxiety GWAS meta-analysis as input and the 1,000 Genomes Project European populations as linkage disequilibrium (LD) reference, posterior variant-level effect sizes were calculated using PRS-CS(34). Global shrinkage parameter ϕ was fixed to $1e^{-2}$. Based on the PRS-CS output, PRS of anxiety in AoU participants was calculated using PLINK 1.9(35).

Statistical Analysis

All numeric variables investigated in the present study were scaled to have a mean of 0 and a standard deviation of 1.

The association of the anxiety PRS with the daily SDANN measurements was estimated using generalized linear mixed models implemented in the R packages *lme4* and *lmerTest*. Given the multiple observations per person, participant IDs were entered into the model as a random effect grouping factor. The participants' age in days at the day of the SDANN measurement, BMI at baseline, sex at birth, and the top 10 within-ancestry PCs were included as covariates. To account for the effect of antidepressants on HRV, we include daily antidepressant exposure as an additional covariate in a second model. To verify the robustness of the association, we performed sensitivity analyses excluding individuals with comorbid conditions (i.e., MI, Ar, CHF, DM, and MDD) and medications (beta blockers and calcium channel blockers) that may also affect HRV.

To explore a potential causal effect of anxiety on SDANN, we employed a one-sample Mendelian randomization (MR) approach in AoU(14). The underlying hypothesis of this approach is that if anxiety has a causal effect on SDANN, the anxiety polygenic risk, which is independent of environmental confounders and strongly associated with anxiety, will have a proportional effect on SDANN, provided that there is no other mechanism that links the genetic susceptibility to anxiety and SDANN (horizontal pleiotropy) (**Figure S1**). In that case, we use the anxiety PRS as an instrumental variable to evaluate the relationship of anxiety to SDANN. The analysis was conducted with the R package *ivreg*, using age, sex, BMI, and the top 10 within-ancestry PCs as covariates. The median daily SDANN per person was used as an outcome and lifetime anxiety diagnosis was used as an exposure.

To understand possible differences across antidepressants in their effect on HRV, we used the R packages *lme4* and *lmerTest* to fit generalized linear mixed models of the association of antidepressant use to daily SDANN accounting for age, sex, BMI, anxiety PRS, and the top 10 within-ancestry PCs. The effect of antidepressants on HRV was investigated considering two parallel approaches; testing the effect of specific antidepressant medications (**Table S2**) and the effect of antidepressant categories (**Table S3**). All antidepressant medications were entered simultaneously in one model to estimate their independent effect on HRV. Antidepressant classes were treated accordingly. In the medication-specific analysis, antidepressants prescribed to fewer than ten people were not investigated. We also excluded SDANN measurement dates where the individual had more than four active antidepressant prescriptions, because this may have been due to errors in the EHR registration (e.g., omitted medication end date).

RESULTS

We analyzed 61,333 data points related to 920 AoU participants of European descent with WGS, Fitbit, and EHR data. Participant baseline characteristics are listed in **Table 1**. The distribution of the daily SDANN values and the number of observations per individual are

shown in **Figure 1** and **Figure S2** respectively. Due to the diverse number of HRV measurements across AoU participants, we verified the relationship between the number of observations and SDANN estimates (**Methods** in **Supplement 1, Table S4**, and **Figure S2**), observing no statistical association for both daily SDANN ($p=0.84$) and median SDANN per person ($p=0.816$).

Table 1. Participant baseline characteristics

| Participant Characteristic | N (%) / Median (IQR) |
|---|----------------------|
| Age at baseline (years) | 51 (24, 79) |
| Sex at birth female | 699 (75) |
| Baseline BMI (kg/m ²) | 28.9 (8.8) |
| Median SDANN per participant (ms) | 109 (37.5) |
| Anxiety disorder diagnosis | 224 (24) |
| Antidepressant exposed | 219 (24) |
| Major depressive disorder | 208 (23) |
| Congestive heart failure | £ 20 ^a |
| Myocardial infarction | £ 20 ^a |
| Beta blocker or calcium channel blocker | 124 (13) |
| Arrhythmias | 142 (15) |
| Any cardiovascular comorbidity or beta blocker exposure | 213 (23) |
| Diabetes mellitus | 97 (10) |

^a Participant counts less than 20 not reported due to AoU data protection policy.

Table 1: Demographic characteristics and comorbid conditions of the All of Us Research Program participants

Figure 1. Daily SDANN Values

Figure 1: Distribution of Fitbit-derived daily SDANN values for the All of Us Participants

Anxiety PRS was significantly associated with reduced daily SDANN (beta = -0.079, 95%CI= -0.13 – -0.028, $p = 0.003$) with no changes in the effect after adjusting for antidepressant use in the model [beta = -0.074, 95%CI=-0.13 – -0.027, $p = 0.003$]. Excluding AoU participants with comorbidities (i.e., MI N = 20; Ar N= 142; CHF N = 20; DM N= 97; MDD N= 208) and medications (beta blockers and calcium channel blockers N = 124) that may affect HRV, anxiety PRS remained statistically significantly associated with reduced daily SDANN (**Table S7**). Among the covariates entered in the model, BMI, age, female sex at birth, and antidepressant use were also associated with reduced daily SDANN (**Table S6** and **Figure S3** in Supplement 1).

The one-sample MR analysis demonstrated that the PRS association could indicate a causal effect of anxiety on reduced SDANN (beta=-2.217, $p=0.03$). The reliability of this estimate is

supported by the fact that the anxiety PRS is a robust instrument ($P = 0.006$). Additionally, SDANN is associated with the variables in our model (Wu-Hausman $P = 0.005$) and the explanatory variables are significant for the model fit (Wald test $P < 0.001$) (**Table S5**).

In antidepressant analysis, venlafaxine ($\beta = -0.12$, $p = 0.002$) and bupropion ($\beta = -0.071$, $p = 0.01$) were associated with reduced SDANN. No other antidepressant medications were found to have a significant effect on SDANN (**Figure 2**). When grouping antidepressants by category, TCAs had the strongest effect on SDANN ($\beta = -0.177$; $p = 8 \times 10^{-4}$) followed by serotonin and norepinephrine reuptake inhibitors (SNRIs) ($\beta = -0.157$; $p = 2 \times 10^{-6}$) and SSRIs ($\beta = -0.069$; $p = 8 \times 10^{-4}$). No statistically significant association was observed for serotonin antagonists and reuptake inhibitors (SARIs; $\beta = 0.044$, $p = 0.16$; **Figure 3**).

DISCUSSION

Anxiety disorders are a clinically heterogeneous group of mental illnesses with a substantial impact on the global burden of disease that was accentuated following the COVID-19 pandemic(36). Consequently, early identification and intervention are urgently needed. Big data analytics can enrich anxiety diagnostic arsenal and refine existing diagnostic approaches(37). HRV derived by hospital-based measurements has been previously proposed as a predictor of treatment response in individuals with anxious depression(38). To screen for anxiety in the general population, more accessible methods of HRV measurement would be valuable. Digital phenotyping can answer the need for real-life longitudinal HRV measurements prior to the disease onset and identification of a disorder, possibly earning a place in anxiety prediction algorithms(39). Before employing HRV as a predictive tool for

anxiety, it is crucial to establish an association independent of comorbid conditions and medications. In this study, we demonstrated that genetic susceptibility to anxiety is associated with decreased SDANN, independently of antidepressant use, cardiovascular comorbidities, DM, and MDD. We additionally provide data supporting a possible causal relationship between anxiety and reduced HRV, supporting the potential use of wearable device-derived SDANN as a predictive tool. To further confirm this, it would be important to test whether the genetic predisposition to reduced HRV may be associated with increased anxiety risk. Unfortunately, at this time it is not possible to perform such analysis; to our knowledge, the only existing HRV GWAS was conducted using HRV measures derived at rest(40). As discussed previously, HRV estimates at rest might reflect distinct aspects of the autonomic function(16, 17).

Beyond dissecting the relationship between HRV and anxiety, we also demonstrated that venlafaxine and bupropion are associated with decreased SDANN independently of anxiety polygenic risk and the use of other antidepressants. These findings support previous evidence; the effect of venlafaxine on HRV was previously reported in a double-blind clinical trial,(41) and bupropion has been associated with decreased HRV in healthy volunteers(42). Given the well-established effect of these drugs on the noradrenergic system(43), our findings are in line with the proposed HRV modulation by brainstem catecholaminergic neurons(43). When we aggregated antidepressants by mechanisms of action, TCAs, SNRIs, and SSRIs were associated with decreased HRV. Both TCAs and SSRIs have been associated with decreased HRV in a recent meta-analysis of randomized placebo-controlled trials (RCTs) and pre-post studies(8). SNRIs have been associated with adverse cardiovascular outcomes, although their effect on HRV as a class has not been investigated to date(44). While our analysis of antidepressant medications expands the knowledge of their effect on HRV, we have to acknowledge the observational nature of our study. Comorbidities and disease severity could simultaneously affect SDANN and drive the clinicians' choice of antidepressants or the prescribed dosage, potentially confounding the

observed effect of the antidepressants on SDANN. Thus, our findings call for further investigation of the role of those medications on HRV using randomized-controlled trials for causal relationships to be established.

Considering the above, the link between HRV, anxiety and antidepressants is complicated by the fact that both disease and treatment affect the outcome in the same direction, making this association challenging to disentangle. The longitudinal 24-hour SDANN values provide a stable metric that supplies the resolution needed in order to investigate variables that change over time, such as antidepressant exposure without requiring hospital-based measurement. Extracting SDANN by minute-level measurements did not allow us to preprocess the inter-beat intervals to remove artifacts or calculate other HRV metrics. Nonetheless, the distribution of SDANN values in our sample is comparable to 24-hour Holter electrocardiogram-derived measures(45-47). Additionally, the anxiety polygenic risk quantifies the genetic predisposition to anxiety in the general population. Of note, our study focused on European individuals, so the generalizability of our findings to other ancestry groups would require further research. As shown in the present study, anxiety polygenic risk is associated with anxiety and antidepressant use, but it is by definition stable over time since birth contrary to the various environmental exposures(48). The significant and robust results of the sensitivity analyses support the association of the anxiety PRS with SDANN, emphasizing the utility and power of genetic instruments in the case of a multifactorial outcome like HRV(49).

In this study, we combined genomic information, wearable device data, and EHRs to investigate the association of HRV with anxiety and antidepressants. Our results provide insights into the impact of anxiety and medications on heart rate variability (HRV), contributing to the study of the comorbidity between mental and physical health. In particular, understanding the mechanisms by which anxiety and antidepressant medications lead to

reduced HRV could contribute to a better understanding of the morbidity and mortality observed among individuals affected by mental illnesses.
