Abstract

Background: In the transport sector, efforts to achieve carbon neutrality may generate public health cobenefits by promoting physical activity.

Objective: This study aims to quantify the health impacts related to active transportation based on four different scenarios leading France toward carbon neutrality in 2050.

Methods: The French Agency for Ecological Transition developed four consistent and contrasting scenarios (Transitions2050 scenarios : S1 to S4) achieving carbon neutrality by 2050 as well as a business-as-usual (BAU) scenario that extends our current lifestyles until 2050, without reaching net-zero. For each Transitions2050 scenario, we distributed the mobility demand for walking, cycling and e-cycling across age groups. Relying on the health impact assessment framework, we quantified the impacts of the corresponding physical activity on all-cause mortality. The impact of each of the carbon neutrality scenarios was determined by comparison with estimates from the BAU scenario.

Results: In S1 and S2 scenarios, volumes of active transportation are projected to increase to fulfil the World Health Organisations recommendations by 2050, while they increase slightly in S3 and decrease in S4. S2 scenario reaches the highest levels of health cobenefits, with 497,000 deaths prevented between 2021 and 2050. This would translate into a life expectancy gain of 3.0 months for the general population in 2050, mainly driven by e-bikes. S1 would provide smaller but important health benefits, while these benefits would be modest for S3. On the contrary, S4 implies 52,000 additional deaths as compared to the BAU scenario, and a loss of 0.2 month in life expectancy.

36 **Discussion:** Different ways to decarbonize mobility in a net-zero perspective may achieve very
37 contrasting public health cobenefits. This study illustrates how the public health dimension may
38 provide a relevant insight in choices of collective transformation toward net-zero societies.

Introduction

39
40

The Paris agreement, adopted in 2015, establish the objective of constraining the rise in average
global temperature to 2°C above preindustrial levels (UNFCCC (United nations Framework
Convention on Climate Change), 21st session 2015). To achieve this, a substantial reduction of 43%
in greenhouse gas (GHG) emissions by 2030 is necessary (IPCC (Intergovernmental Panel on Climate
Change) 2023). The sixth report from the Intergovernmental Panel on Climate Change (IPCC)
highlights the importance of numerous actions that effectively reduce our carbon footprint while
concurrently promoting human health. These health co-benefits manifest across several dimensions
such as diet, transport, energy supply or green and blue infrastructures (IPCC (Intergovernmental
Panel on Climate Change) 2023).

The transport sector accounted for approximately 15% of anthropogenic GHG globally in 2019 (IPCC
(Intergovernmental Panel on Climate Change) 2023). In France, it contributes up to 31% of GHG
emissions (HCC (The High Council on Climate) 2021). Amongst the many existing levers to limit these
emissions (electrification of the energy supply, increased vehicle occupancy, lower transport
demand…), some have the potential to yield health co-benefits. Among those, shifting to active
modes of transportation offers the additional advantage of mainly relying on local decisions such as
reallocation of existing infrastructures and land use planning (Stappers et al. 2023).

Active transportation encompasses essential daily activities (e.g., commuting to work, visiting the
doctor, shopping) as well as leisure activities (e.g., cultural outings, sports) and has indeed been
identified as a lever for achieving socio-economic, air quality, and public health co-benefits (IPCC
(Intergovernmental Panel on Climate Change) 2023). However, physical activity levels worldwide
have failed to meet international recommendations, affecting both adolescents and adults (Guthold
et al. 2018). In high-income countries, 9.3% of overall mortality can be attributed to physical
inactivity (Katzmarzyk et al. 2021). Insufficient physical activity also incurs substantial monetary costs
for public and private healthcare systems and households while leading to decreased productivity
(Ding et al. 2016). A 2017 study focusing on urban populations estimated that meeting international
guidelines on physical activity, air pollution, noise, heat, and access to green spaces could prevent
20% of deaths. Among these factors, physical activity yielded the largest proportion of preventable
deaths (Mueller et al. 2017).

The health benefits associated with active transportation may be substantiated by various health
impact assessment methods that consider diverse parameters, regardless of the geographical
context (Mueller et al. 2015). Institutions and organisations have devised prospective pathways
outlining the necessary transformations required for the societies to attain the objectives of the Paris
agreement. Numerous studies quantify the health impacts of active commuting in prospective
scenarios, with a majority conducted in Europe, North America or Oceania, primarily focusing on
urban areas (Mueller et al. 2015; Rojas-Rueda et al. 2016). Nevertheless, to the best of our
knowledge, only one study has been conducted at the national level in France, quantifying the
impacts of a single scenario compared to the baseline levels of 2021 (Barban et al. 2022).

In this study, we quantified the health impacts related to physical activity through active
transportation based on four consistent and contrasting scenarios leading France toward carbon
neutrality in 2050.

Methods

The ADEME Transition scenarios

In 2021, ADEME (The French Agency for Ecological Transition) released the outcomes of a prospective project "Transitions2050", describing four scenarios (S1 to S4). Each of these scenarios is designed to achieve carbon neutrality by 2050 in metropolitan France following distinct trajectories corresponding to different societal choices (Figure 1) (The French Agency for Ecological Transition). Additionally, a business-as-usual scenario (BAU) was formulated, representing a projection of our current lifestyle trends until 2050, without achieving carbon neutrality. It partly corresponds to an extension of certain past trends and partly to evolutions already underway.

Figure 1 - Summary of ADEME's prospective carbon neutral scenarios.

S1 FRUGAL GENERATION

Significant changes in the way we travel, keep warm, eat, buy and use equipment will occur to achieve carbon neutrality only with natural sinks (forests and soils), thus preserving the associated ecological services.

S2 REGIONAL COOPERATION

To achieve carbon neutrality, society relies on a progressive but steady change of the economic system towards a sustainable path combining sufficiency and efficiency.

S3 GREEN TECHNOLOGIES

Technological development provides more of the answers to environmental challenges than changes towards more sufficient consumption patterns.

S4 RESTORATION GAMBLE

Society places its trust in its ability to manage and even repair social and ecological systems with more material and financial resources to maintain a liveable world. Carbon capture and storage technologies, which are essential, are uncertain and consume electricity.

Credit: @ADEME - Transition(s) 2050 - Illustrations : S. Kiehl

Each Transitions2050 scenario describes the evolution of the main energy consumption drivers over
time, especially the demand for transportation for various modes of transportation (Table 1). Within
these estimates, three active modes are considered: cycling, E-cycling and walking, without
accounting for recreational activity. Note that the estimates for walking encompass distances
covered while transitioning to or from another mode of transport, especially public transportation
(e.g train or bus). For each active travel mode, the scenarios express the yearly national demand in
terms of Giga passenger-kilometres (Gpkm) at five-year intervals over the period 2015-2050. For this
study, passenger-kilometres values were linearly interpolated for each year within the intervals.
104

105   Table 1 – Transport sector and active mobility in ADEME's prospective scenarios

Scenarios	**Frugal generation (S1)**	**Regional cooperation (S2)**	**Green technologies (S3)**	**Restoration gamble (S4)**	**Business-as-usual (BAU)**
Decarbonation of the transport sector	A significant drop in transport demand. Modal shift and vehicle occupancy expand.	Modal shift at the heart of the transition. More vehicle occupancy and a decrease in transport demand.	Efforts are mainly applied to energy efficiency and decarbonation of the energy production.	Energy production and digital technologies drive the transition. Energy efficiency also improves.	Projection of our present lifestyles.
Evolution of per-capita transport distances (in km) from 2015 to 2050	Walk : +15 % Total cycle : +730 %	Walk : +25 % Total cycle : +1,007 %	Walk : +6 % Total cycle : +336 %	Walk : -8 % Total cycle : +92%	Walk : +1 % Total cycle : +92 %

116
117

Age-specific allocation of active transport demands

For each Transitions2050 scenario and mode of transportation, the passenger-kilometres were distributed among age groups according to the mode-specific age distributions observed in the 2019 French mobility survey (Ministry of Ecological Transition).

In addition, we allocated the total number of kilometres cycled between E-bikes and mechanical bicycles differently based on age groups. This allocation was done in order to achieve two objectives: i) replicate the observed 6.7-year age difference between E-bikers and cyclists as reported in a recent multi-country study (Castro et al. 2019), and ii) reflect the changing relative contribution of E-bikes to the total cycling distance over time, as assumed in each scenario.

Further details regarding these calculations are provided in the Supplementary Materials.

Demographic projections

Population projections, including mortality and life expectancy, for different years and age groups, were accessed from publicly available data provided by the French national institute of statistics and economic studies (INSEE). These same data were also used by ADEME in the design of all their transition scenarios.

Health impact assessment

We relied on international guidelines to model and report the health effects associated with active transportation of the Transitions2050 scenarios for metropolitan France over the 2021-2050 period (Hess et al. 2020).

For each age group, yearly distances travelled were converted into exposure times for walking, cycling or E-cycling using the following average speeds, respectively: 4.8, 14.9 and 18.1 $km.h^{-1}$ (Egiguren et al. 2021; Götschi et al. 2020). First, we compared the resulting total duration of active travel to international recommendations for weekly moderate physical activity, averaged over the entire adult population.

The health impacts (number of deaths averted) generated by physical activity associated with active transportation were calculated, using a linear dose-response function between duration spent in active transportation and the reduction in all-cause mortality, weighted by the specific mortality rate and size of the population:

$$Nprev_{a,s} = (1 - RR_{REF}) \times \left(\frac{Specific\ duration_{a,s}}{Reference\ duration} \right) \times MR_a \times POP_a$$

With:

$Nprev_{a,s}$: Number of death prevented

RR_{REF} : Relative risk of all-cause mortality associated with the reference duration of active travel (Kelly et al. 2014).

Specific duration$_{a,s}$: Projected in the scenarios and distributed across age groups

Reference duration : 168 minutes for walking and 100 minutes for cycling as estimated in a meta-
analysis of 18 cohorts (Kelly et al. 2014). This correspond to an energy expenditure of 11.25
MET.hour.week^{-1}.

MR_a : Specific mortality rate of an age categorie a

POP_a : Population of the age category a

We used a relative risk (RR$_{REF}$) of 0.89 for all-cause mortality when engaging weekly in 168 minutes of
walking, with maximum risk reduction of 30%, and a relative risk of 0.90 for 100 minutes of cycling,
with a maximum risk reduction of 45%. Health impacts are therefore capped above 460 minutes of
walking and 447 minutes of cycling (Kelly et al. 2014). We constrained the benefits associated with
physical activity to the population aged between 20 and 89 years. This restriction was made based on
the fact that the relative risk estimates for cycling and walking were extrapolated from studies
encompassing individuals within the age range of 20 to 93 years (Kelly et al. 2014) and the data used
for age distribution of cycling distances were collected from individuals aged between 15 and 89
years (Ministry of Ecological Transition). The assumed ratio of energy expenditure between E-bikes
and bikes was 0.90, as recently used by studies conducted at European and international city levels
(Egiguren et al. 2021). The impacts were evaluated for each age group, taking into account the
respective population size and mortality rate. The total count of deaths prevented by each scenario
was obtained, together with the number of years of life lost (YLL) prevented, by subtracting from the
estimated number of deaths prevented in this scenario the estimated number of deaths prevented in
the BAU scenario. Finally, based on the estimate of the number of deaths prevented, life tables were
generated in order to compute the life expectancy in each scenario.

Monetizing the health impacts

We further estimated the intangible costs associated with the health impact of each scenario, using
the value of a statistical life year (VSLY) that is recommended in France for the socioeconomic
assessment of public investments (Emile 2013). In France, the VSLY is projected to be €151,000 in
2025, and this figure is anticipated to increase to €202,000 by 2050.

The VSLY was multiplied by the number of YLL prevented to calculate the monetary impacts of
mortality risk reduction. All monetarized values were expressed in €$_{2022}$.

All the estimates were presented alongside uncertainty intervals (UI), which were determined using
the lower and upper bounds of the 95% confidence interval (CI) of the RR used.

Sensitivity analyses

We performed five distinct sensitivity analyses. First, we explored a more favourable RR associated
with cycling (0.81 instead of 0.90 per 100 minutes of cycling), as estimated by a recent meta-analysis
(Zhao et al. 2021). Second, we explored alternative walking and cycling speeds, respectively 3.6 and
13 km.h^{-1} (The French Agency for Ecological Transition). Third, we investigated an alternative ratio of
0.78 between E-bike and cycling energy expenditures (Berntsen et al. 2017). Fourth, for scenarios S1
and S2, we assumed that the high increase of cycling overall would affect the demography of cyclist
toward a flatter age distribution, as those observed in countries with a high cycling culture, such as
Denmark. We therefore evolved gradually between 2021 to 2035 the distribution of age-specific
contribution of kilometres cycled from the levels observed in France (Ministry of Ecological
Transition) to those reported in Denmark (Center for Transport Analytics, Transport) (see

supplementary materials). Lastly, we constrained the benefits of active transportation to the age
range of 20 to 75 years, as opposed to the wider scope of 20 to 89 years in the main analysis. All
analyses were conducted using the R software version 4.2.3; all data and codes are publicly available
at: https://github.com/LeoMoutet/HIA-transport.

Results

Projection of active transport

Time changes in transport demand from 2021 to 2050 are presented in supplementary materials (Figure S1) for each mode of active transport and scenario.

Figure 2 compares the estimated average weekly durations of active transportation obtained under each scenarios by 2035 and 2050 with both the 2015 French situation and the minimal recommendations set by the World Health Organization (WHO), that is, 150 minutes of moderate-intensity aerobic physical activity per week. In 2015, the active transportation levels in the French population allowed for a weekly average of 80 minutes of moderate-intensity aerobic physical activity (The French Agency for Ecological Transition). In the S2 scenario, in 2035, the average levels of physical activity through active transportation alone are expected to attain the minimal WHO recommendations. The S1 scenario nearly achieves these levels by 2035 and surpasses them by 2050. In contrast, the S3 scenario falls short of reaching the minimal recommended levels of physical activity, both in the medium term (2035) and the long term (2050). Both the BAU scenario and the S4 scenario project minimal increases in active transportation compared to 2015, and fail to reach WHO's minimal recommendations, even by 2050. These results are detailed by age groups in supplementary materials (Figure S2).

Figure 2 - Duration (averaged for the 20-89 years old) of physical activity generated by active transportation in 2035 and 2050 compared to the French levels in 2015 (all estimated by ADEME Transition scenarios) and the WHO guidelines for moderate physical activity [26].

Quantitative health impact assessment

The time-varying health effects expected in each scenario are presented in Figure 3 as numbers of prevented deaths and YLL compared to the BAU. The disparities in health impacts among scenarios become more pronounced as time progresses. From 2030 to 2040, the benefits of S1 and S2 scenarios experience a large increase, while the benefits of S3 scenario show a more linear progression. On the other hand, S4 scenario has negative impacts that intensify over time and remain noticeable for all age groups above 50 years old. Deaths prevented by scenarios S1-S3 are highest in the 80-89 age group, and YLL prevented increase for younger ages, plateau for the 40-59 and the 60-79 years old age groups, and are limited amongst 80-89 years old.

For all age groups, the benefits of S2 surpass all other scenarios while the benefits of S1 outweigh those of S3. The YLL metric makes these benefits apparent for younger age groups (from 20 years old on). The health impacts of S4 remain small, though negative.

Figure 3 - Deaths prevented (A and C) and YLL prevented (B and D) by year (A and B) and age group (C and D, cumulative for the 2021-2050 period) for each transition scenario compared to the BAU.

Figure 4 distinguishes the health benefits of the different scenarios by type of active transportation. Starting from 2030 onwards, scenarios S1 and S2 demonstrate a rapid increase in the health benefits associated with E-cycling, while its progression in S3 is more linear. The health benefits in the first scenario mainly come from cycling, with more or less equal contributions of classical and E-cycling throughout the period from 2021 to 2050. In scenarios S2 and S3, E-cycling emerges as the mode of active transportation contributing to the majority of health benefits, while walking and cycling provide similar benefits each year. On the other hand, scenario S4, which is comparable to the BAU scenario in terms of cycling mobility, exhibits lower levels of walking. Consequently, the health detriments observed in scenario S4 can be entirely attributed to the decrease in pedestrian mobility.

Figure 4 - Years of Life Lost (YLL) prevented as a function of time and type of active transportation, under (A) scenario S1, (B) scenario S2, (C) scenario S3, and (D) scenario S4.

Figure 5 presents the annual health and economic benefits of each scenario at medium (2035) and long (2050) term. Here again, scenario S2 shows a larger impact over all other scenarios, S1 exhibits a superiority over scenario S3, and scenario S4 has detrimental health impacts as compared to the BAU. The number of deaths prevented in 2050 by active transportation reaches 25,569 [14,773-37,221] with the trajectories projected for scenario S2, 18,436 [10,645-26,067] with scenario S1 and 6,300 [3,739-9,117] with scenario S3. Scenario S4 would induce an additional 2,658 [962-4,106] deaths.

Life expectancy of the French population in 2050 would improve by 3.0 [1.9-4.3] months by achieving modal shift as described in scenario S2, 2.2 [1.3-3.1] months with scenario S1, 0.8 [0.5-1.1] months with scenario S3 and would decrease by 0.2 [0.1-0.3] months with scenario S4.

For 2035, the annual corresponding monetarized health benefits (based on the YLL) range from €33.9 [IC: 19.7-48.5] billion with scenario S2 to €7.9 [IC: 4.8-11.2] billion with scenario S3. Scenario S4 corresponds to a net detrimental monetarized health impact of €2.5 [1.0-3.9] billion.

Figure 5 - Deaths prevented (A and B), gain in life expectancy (C and D) and cost avoided (E and F) by 2035 (A, C and E) and 2050 (B, D and F).

Sensitivity Analyses

Table 2 summarizes the results of our sensitivity analyses. Overall, the parameter choice which affects the most our estimates is the RR value for cycling. Assuming a more favourable RR leads to notable increases in the YLL estimated, around +50 to +70%. Modifying the speeds of walking and cycling has less but substantial effects of about +20% in the YLL prevented. By lowering the speeds, the duration of exposure to physical activity is extended, leading to higher health impacts. The third sensitivity analysis, focusing on the ratio of energy expenditure provided by an E-bike compared to a mechanical one slightly reduces the health impact, by less than 10% of YLL prevented. In scenarios characterized by high levels of cycling (S1 and S2), using the gradual shape of the age distribution of cycling kilometres of France in 2021 to Denmark in 2035 (and on to 2050) leads to a minor decrease in the number of prevented YLL. Considering Denmark's relative age contribution for cycling kilometres leads to less deaths prevented in older age groups (Supplementary materials, figure S5), and so has limited impacts on YLL prevented. Restricting the health effects to individuals below the age of 75 reduces the YLL prevented ascribed to active transportation by about 20%.

284 For each analysis and any choices of the parameters, the ranking of scenarios according to their
285 health impacts remained unchanged, with S2 as the most beneficial scenario, followed by S1 and
286 then S3, while S4 yielded negative health impacts.

288 Table 2 - Health impacts of active transportation for ADEME's scenarios. Main and sensitivity
289 analysis.

	Cumulative YLL prevented for 2021-2050 [CI], in million			
	S1	S2	S3	S4
Main analysis	3.9 (2.2, 5.5)	5.7 (3.3, 8.1)	1.4 (0.8, 2.0)	-0.4 (-0.7, -0.2)
RR_{cycle} = 0.81 (Zhao et al. 2021)	6.7 (3.1, 10.5)	9.7 (4.6, 15.7)	2.4 (1.2, 4.0)	-0.4 (-0.7, -0.2)
Alternative speeds: walking = 3.6 km.h^{-1}; cycling = 13 km.h^{-1} (The French Agency for Ecological Transition)	4.6 (2.6, 6.5)	6.7 (3.9, 9.7)	1.6 (9.8, 2.3)	-0.6 (-0.9, -0.2)
Ratio $MET_{E-cycle/cycle}$ = 0.78 (Berntsen et al. 2017)	3.7 (2.2, 5.5)	5.2 (3.3, 8.1)	1.3 (0.8, 2.0)	-0.4 (-0.7, -0.2)
Age distribution of cycling evolves with high levels of cycling (S1 and S2)*	3.8 (2.2, 5.3)	5.4 (3.2, 7.8)	1.4 (0.8, 2.0)	-0.4 (-0.7, -0.2)
No effect >75 years old	3.2 (1.8, 4.5)	4.6 (2.8, 6.7)	1.1 (0.7, 1.6)	-0.3 (-0.5, -0.1)

290 YLL = Years of life lost ; CI = Confidence interval ; RR = Relative risk ; MET = Metabolic equivalent of task.
291 *The distribution of age-specific contribution of cycling kilometres evolve gradually between 2021 and 2035 from the levels
292 observed in France to those reported in Denmark (Supplementary materials).

Discussion

Main results

In this study, we highlight the widely varying potential health benefits of transport transition pathways towards carbon neutrality, through their impact on active transport. Future pathways promoting modal shift to active modes of transportation facilitate the attainment of the minimal recommendation on physical activity set by the WHO solely through transport activities. Conversely, policies wagering on future technological developments to attain carbon neutrality are likely to intensify the lack of physical activity and its harmful health impacts in the general population. According to the extent of modal shift, and compared to the BAU, health impacts at the 2035 horizon may range from 19,000 deaths prevented to 2,000 additional deaths, representing respectively €34 billion annual savings and €3 billion additional mortality costs. Qualitative results and the ranking of Transitions2050 scenarios remained consistent through several sensitivity analyses.

Literature comparison

For all scenarios, the majority of health benefits may be explained by an achievable increase in cycling mobility, particularly through the use of E-bikes. The most optimistic scenario reaches 20 kilometres cycled and 7 kilometres walked per person weekly, representing roughly 20 minutes per day of active transportation. Such increase in active transportation seem considerable as compared to the levels reported before 2020. However, they remain lower to those reported in other European countries: In Netherlands, active transportation represent between 24 and 28 minutes daily (Fishman et al. 2015) and more than 50% of trips <2 kilometres and 30% of trips between 2 to 5 kilometres are undertaken using bicycles (Goel et al. 2021). This highlights the margin of progression for active transportation in France, where only 5% of the active population uses a bike for trips covering less than 5 kilometres, while 60% opt for a car (Chantal Brutel, Jeanne Pages 2021). The anticipated levels of active transportation in S1 and S2 scenarios therefore appear to be quite achievable.

The method we used for quantifying health and economic impacts follows the recommended steps and parameters outlined by the WHO and environmental economists. These approaches are widely described and employed in various scientific studies (Emile 2013; Götschi et al. 2020; Smith et al. 2021). A health impact assessment study on the transport sector was previously conducted in France using a similar method (Barban et al. 2022). The scenario explored in this study projected active transportation levels similar to those observed in the S1 scenario, and the estimated health impacts were similar to those we obtain. Studies comparing multiple scenarios consistently demonstrate significant differences in the health impacts of active transportation: Climate policy strategies that prioritize health-promoting pathways and are built upon the behaviours of the population yield more significant health benefits (Hamilton et al. 2021; Milner et al. 2023).

Preventing, as we predict in scenario S2, 19,000 deaths annually by 2035 solely through deliberate decisions in the development of the transportation sector holds significant importance for public health prevention as it corresponds to 2.8% of all-cause mortality projected for this year (INSEE). Indeed, in comparison, in France, it is estimated that exposure to PM2.5 is responsible for 40,000 deaths annually (Santé publique France 2021) while heat-attributable deaths reached up to 7,000 in 2022 (Santé publique France 2023). In the transport sector, all road-related fatalities in France range between 3,000 and 4,000 deaths annually (excepted in 2020 and 2021) (ONISR (Observatoire national interministériel de la sécurité routière) 2023). From a benefit-cost perspective, based on a UK case-study, the economic gain of prevented mortality generated by an additional 267 regular cyclists per kilometres of a new separated cycleway breaks even on the costs of construction (Candio and Frew 2023).

The adoption of electric modes of transportation is widely recognized as a strategy for mitigating emissions within the transportation sector. However, it is important to acknowledge that electric vehicles, along with the high battery metals demand (European Federation for Transport and Environment 2023), can also contribute to pollutant emissions through the dispersion of road dust particles and the degradation of tires and brakes wear (Bourliva et al. 2017). In the transport sector, modal shift and decarbonation of the energy supply can yield larger health co-benefits (Milner et al. 2023). The promotion of E-bikes is a cost-effective approach to reduce transport associated carbon emissions while improving health and mobility (Jenkins et al. 2022). The allocation of more areas to bicycle infrastructure can also optimize the utilization of public space (Gössling et al. 2016).

Other outcomes have to be taken into account when outlining health effects of modal shift such as air pollution, road injuries or noise. Regardless of the specific assumptions, the health benefits of active transportation consistently outweigh the potential adverse effects stemming from exposure to air pollution and traffic-related incidents (Mueller et al. 2018). Among various modes of transportation, car users exhibit highest levels of exposure to air pollutants such as PM2.5, black carbon, and CO (de Nazelle et al. 2017). The association with road injuries depends greatly on the assumptions made on the fatality and injury rates of cyclists (Quam et al. 2017) as well as the quality of transport infrastructures (WHO 2022). Furthermore, each incremental shift from cars to bicycles corresponds to a noteworthy decrease in pollutant emissions (Bernard et al. 2021). For instance, it has been estimated that an individual who replaces one car trip per day with a bicycle trip over 200 days can reduce their CO_2 emissions by 0.5 tons per year (Brand et al. 2021). Noise pollution would also benefit from modal shift, which would yield positive impacts on health-related quality of life, mediated by annoyance and sleep disturbance (Héritier et al. 2014). It is also expected that a general increase of physical activity reduces morbidity related to cardiovascular risks, cancer, osteoporosis, depression and low back pain (Miller et al. 2016). Further impacts related to quality of life can also benefit from active transportation such as work performance and productivity (Ding et al. 2016).

Limitation

Using the transport demand as a proxy for physical activity allows for a quantification of health impacts associated with specific active modes of transport but does not encompass several variations in the population. For example, given the expectation that scenarios S3 and S4 would limit active transportation primarily to those who are already physically active, while scenarios S1 and S2 would promote active transportation for a broader population, including individuals who are sedentary, a more targeted distribution of transport demand could be achieved. This distribution would involve a heterogeneous allocation of distances within age groups. By implementing such an allocation strategy, the differences in health impacts between high cycling (S1, S2) and low cycling (S3, S4) scenarios could be amplified. Another limitation linked to this proxy is that the physical activities performed out of transport context are not taken into account, despite their anticipated distinct evolution across scenarios. However, several studies suggest that active transportation adds to rather than replaces other physical activities (Laeremans et al. 2017).

Using a relative risk from a meta-analysis provides a robust association between physical activity and mortality reduction but does not allow to specify distinct relative benefits based on age, gender, or socio-occupational category. A recent meta-analysis showed no significant differences in the association of cycling with all-cause mortality for gender groups and among individuals aged above or below 50 years (Zhao et al. 2021). Additional cohort studies are needed to assess the potential heterogeneity of the association between more specific age groups and socio-occupational categories.

Our analysis incorporates a dose-response functions that account for cycling and walking-related
mortality, primarily including impacts from physical activity, but also from air pollution exposure and
road injuries (de Nazelle et al. 2011). Higher modal shift scenarios lead to an accelerated reduction in
air pollution exposure, while evidence shows a non-linear relationship between the number of
cyclists and road injuries (Jacobsen et al. 2015). Using the same dose-response function across years
may lead to underestimating health benefits and narrowing the differences between scenarios.

Our results are calculated from a projected scenario, the BAU. This inherent uncertainty may
introduce variability in the absolute results of each scenario, yet it does not alter the relative
hierarchy of their respective impacts.

All in all, it is important to acknowledge that a health impact assessment study only provides
theoretical estimates of health and economic impacts, and that its quantitative results should not be
over-interpreted. However, the magnitude of effects and the comparison of scenarios allow for a
better interpretation of the co-benefits and potential implications of specific public policies.

Conclusion

Different carbon neutral trajectories imply distinct health benefits, this holds particularly true within
the transport sector. The implementation of public policies promoting modal shift effectively
improves population health while reducing the use of fossil fuels and pollutant emissions. In France,
directing transportation towards active modes would yield significant health co-benefits. Transition
trajectories primarily relying on technological interventions offer minimal benefits and may even
exacerbate the lack of physical activity in the population. In a context of reaching towards carbon
neutrality, these results may help guide decision-makers in the choice of optimal transition
strategies.

Acknowledgments

411 We are thankfull to Stephane Barbusse (ADEME - The French Agency for Ecological Transition) for
412 useful elements and discussions regarding the ADEME Transitions2050 scenarios.

Authors contributions

415 PQ and KJ conceived the design of this study. LM produced output, figures and tables. AB contributed
416 to data acquisition. LM, LT and KJ interpreted the results and wrote the original draft of the article.
417 AB and PQ contributed to critical feedbacks on the methodology and interpretation of the results.

4 SCENARIOS
for a carbon neutral society

S1 FRUGAL GENERATION

Significant changes in the way we travel, keep warm, eat, buy and use equipment will occur to achieve carbon neutrality only with natural sinks (forests and soils), thus preserving the associated ecological services.

S2 REGIONAL COOPERATION

To achieve carbon neutrality, society relies on a progressive but steady change of the economic system towards a sustainable path combining sufficiency and efficiency.

S3 GREEN TECHNOLOGIES

Technological development provides more of the answers to environmental challenges than changes towards more sufficient consumption patterns.

S4 RESTORATION GAMBLE

Society places its trust in its ability to manage and even repair social and ecological systems with more material and financial resources to maintain a liveable world. Carbon capture and storage technologies, which are essential, are uncertain and consume electricity.
