Abstract

BACKGROUND: Capnography is one of the most important respiratory monitoring tools used in

EMS because changes to end-tidal CO_2 ($ETCO_2$) generally precede blood oxygen desaturation,

and waveform morphology can be used to assess bronchial patency. Many of capnography's

indications overlap with those of continuous positive airway pressure (CPAP) therapy. However,

there are currently no convenient methods to administer CPAP while using capnography, and no

peer-reviewed studies have examined combining the two technologies in the prehospital setting.

METHODS & FINDINGS: Two types of capnography sampler were used to investigate how

$ETCO_2$, capnogram shape, and respiration rate (RR) are affected by applying a CPAP mask both

with and without oxygen flowing. A traditional nasal-oral cannula (NC) sampler, as well as a novel

sampler that does not break the seal between the CPAP mask and the patient's face (called the

CPAP-Capnography Adapter, or CCA), were evaluated on a Human Patient Simulator (HPS). No

significant differences between the NC and CCA were found for $ETCO_2$ and RR percent error.

Placement of a CPAP mask without turning on O_2 increased $ETCO_2$. During CPAP therapy, the

two samplers maintained their RR measurement accuracy, but $ETCO_2$ values were significantly

reduced and the capnogram depicted an increased β-angle with severe blunting of the inspiratory

downstroke.

CONCLUSIONS: The HPS had set-point $ETCO_2$ and $PaCO_2$ values, indicating that the local CO_2

concentration at the nares was diluted during CPAP and no longer accurately reflected the

simulated subject's breathing. The compromise in waveform morphology could be overcome by

further research into interpreting capnogram differences during CPAP between healthy patients

and those with respiratory pathologies. However, at this time, our results show that $ETCO_2$ values

and capnogram shape should be interpreted with caution during CPAP.

Key Words: End-tidal carbon dioxide, capnography, capnometry, oxygen therapy, noninvasive

ventilation, continuous positive airway pressure, prehospital, emergency medical services

Abbreviations:

EMS - Emergency Medical Services

CO_2 - Carbon Dioxide

CPAP - Continuous Positive Airway Pressure

$ETCO_2$ - End-Tidal Carbon Dioxide (mmHg)

$PaCO_2$ - Partial Pressure of Arterial Carbon Dioxide (mmHg)

SpO_2 - Blood Oxygen Saturation

RR - Respiration Rate (breaths/min)

NC - Nasal-Oral Cannula

CCA - CPAP-Capnography Adapter

MAP - Mean Arterial Pressure

HPS - Human Patient Simulator

PEEP - Positive End Expiratory Pressure

Introduction

Respiratory issues are among the most common causes of 911 calls in the United States.(1) Once on scene, EMS personnel interview the patient and use vital signs—such as heart rate, blood pressure, respiration rate (RR), pulse oximetry, and capnography—in addition to their physical exam findings to determine possible causes for their breathing difficulties. Capnography is particularly beneficial as it can typically detect changes to a patient's breathing before pulse oximetry.(2–4) For example, one study found that, for acute respiratory events, abnormal $ETCO_2$ results were observed before SpO_2 changes or observed hypoventilation in 70% of cases.(2) Pulse oximetry is also known to overestimate oxygen saturation in patients with darker skin.(5–7) Capnography's physiological relevance stems from its correlation with $PaCO_2$, which regulates the respiratory drive. Directly measuring $PaCO_2$ requires an interventional test that is not practical in the prehospital setting, such as arterial blood gas analysis.(8) There is some debate surrounding the correlation of $ETCO_2$ to $PaCO_2$, but several studies have found good correlation in healthy patients and patients with compromised pulmonary function who are spontaneously breathing.(9–12) Capnography has been shown to be a valuable screening tool for mortality predictions in patients with sepsis.(13,14) Also, in penetrating trauma patients, capnography measurements correlate with serum lactate levels (an indicator of tissue hypoxia and shock) and can predict the odds of the patient requiring operative intervention.(15) See **Fig. 1B & 1D** for example capnograms.

Figure 1. Capnography and Continuous Positive Airway Pressure (CPAP). (A) Nasal cannula (NC) commonly used for prehospital sidestream capnography sampling. (B) Example capnogram for a healthy individual (i) and an individual with bronchospasm (ii); peaks indicate exhalations while troughs indicate inhalations, and the end of the exhalatory plateau yields the $PETCO_2$ measurement (labeled with a star). For the first waveform, phases I-IV are labeled, along with α- and β-angles. (C) Common prehospital CPAP

setup with NC placed below the mask for capnography sampling; CO_2 gas line is circled in purple. (D)

Example EMS monitor depicting a capnography waveform; CO_2 gas line insertion is circled in purple;

standard orange capnography port (not shown) is used for insertion.

Prehospital capnography is most commonly used for validating endotracheal tube

placement,[16] as well as helping identify asthma, chronic obstructive pulmonary disease

(COPD), pulmonary embolism (PE), and congestive heart failure (CHF).[17–19] The morphology

of the capnogram is crucial for assessing bronchial patency as bronchospasm tends to yield a

"shark fin" waveform (prolonged phase II with increase or loss of α-angle),[20,21] which is

depicted in **Fig 1B.ii**. Monitoring of the waveform is currently used to assess response to

bronchodilators.[20,22] Prehospital indications for CPAP strongly align with those of capnography

and include CHF, COPD, asthma, acute bronchitis, pneumonia, and near-drownings with signs

of pulmonary edema.[23,24] Prehospital CPAP has been shown to improve patient outcomes by

reducing the need for intubation (and thus decreasing the likelihood of developing ventilator-

associated pneumonia),[25] improving vital signs, and reducing myocardial damage—its use is

also associated with reduced mortality.[24,26] Using capnography to monitor the effectiveness of

CPAP would allow for the rapid determination of ineffective therapy and a quick decision to be

made regarding switching to an invasive option.[27,28] This would also align with the 2011 AARC

Clinical Practice Guideline on capnography, which recommends its use for monitoring response

to therapies that improve the ventilation-perfusion (V/Q) ratio.[23]

Despite these points, the two technologies are not currently easily compatible. Common

EMS cardiac monitors with built-in sidestream capnography sensors, such as the Physio-Control

LIFEPAK-15, are used with a nasal-oral cannula (NC) sampler for spontaneously breathing

patients, and an in-line sampler for intubated patients.[27,29] Non-invasive ventilation (NIV)

dilutes exhalations, so sampling as close to the nares/mouth as possible is best.[27] Thus, using

an NC sampler is generally preferred during NIV.[30] However, placing a cannula beneath a

CPAP mask is not ideal as it allows gas to escape at the location where the sampling line exits

the mask;(27) significant leaks are problematic as they decrease CO_2 elimination and $ETCO_2$

values.(30) Despite this, due to anecdotal evidence, some EMS education sources recommend

using the NC sampler for capnography during CPAP,(31–33) and EMS systems have already

added this recommendation to their protocols.(34) Thus, in this article, the efficacy of monitoring

capnography during prehospital CPAP will be analyzed on three simulated patients using a

Human Patient Simulator (HPS). To overcome the issue of breaking the seal between the CPAP

mask and the patient's face, this study will introduce a novel sampler—called the CPAP-

Capnography Adapter (CCA)—and compare its performance to the NC. Overall, this article will

investigate if applying a CPAP mask while monitoring capnography with either an NC or the novel

CCA sampler alters the capnogram, $ETCO_2$ readings, or respiration rate.

Materials and Methods

CPAP-Capnography Adapter (CCA) Design Process & Manufacturing

A novel method for measuring capnography during CPAP was invented and tested

alongside the nasal-oral cannula method (see **Fig. 2**). The new method involved attaching an

elbow-shaped adapter to a prehospital CPAP setup between the mask and flow regulator. To

ensure an air-tight seal, flat ring seals were created out of duct tape and applied to each end of

the elbow (functioning similarly to square profile O-rings). A nasal sampling element was fed

through this adapter and into the mask, allowing for sidestream capnography sampling. To

prevent the nasal sampler's tubing from getting crimped by the elbow as it passed into it, a short

internal guide tube was added to provide greater support. The nasal sampler base slid onto

existing CapnoLine® tubing containing a standard orange capnography plug; the sampler fit

snugly via friction but was further secured via duct tape. Combined, this setup is referred to as

the CPAP-Capnography Adapter (CCA).

Figure 2. CPAP-Capnography Adapter (CCA) manufacturing & experimental setup. (A)

Stereolithography (SLA) 3D printing process used for the CCA. (B) Labeled diagram of CCA. (C) Labeled

diagram of CCA integrated into a prehospital CPAP setup. (D) Example of CAE Healthcare Human Patient

Simulator (HPS) output display, including $ETCO_2$ set-point, modeled respiration rate (RR), modeled SpO_2,

modeled heart rate (HR), and modeled blood pressure (BP). (E) CCA applied to the HPS without a CPAP

mask. (F) CCA integrated into a prehospital CPAP setup and applied to the HPS.

The CCA elbow and nasal sampler were designed using OnShape Computer-Aided

Design (CAD) software and printed with a Formlabs Form 2 stereolithography (SLA) 3D printer

(see **Fig. 2A**). Engineering sketches are provided in **Fig. S1**. Formlabs Clear V4 resin was

selected as the elbow material due to its translucency and rigidity.(35) Formlabs Elastic 50A resin

was selected as the nasal sampler material due to its translucency and flexibility,(36) the latter

property allowing for the accommodation of various nose sizes. After printing, an isopropyl alcohol

(IPA) bath was used to vigorously wash parts for 15 minutes. Then, an IPA-filled syringe was

used to clear excess resin from small channels, and the parts were soaked in a clean IPA bath

for an additional 15 minutes. Next, an ultraviolet (UV) light & heat cure was conducted according

to the manufacturer's guidelines (power density: 1.25 mW/cm^2; LED centered at 405 nm; 60 °C

for 20 minutes for Elastic 50A and 60 minutes for Clear V4).(35–37)

Materials

A stock CPAP kit containing a Pulmodyne O_2-MAX™ and Curaplex O_2 Max Trio BiTrac

ED Mask was used. For all conditions, CPAP tubing was fully contracted to standardize dead

space, and the PEEP valve was set to 10 cm H_2O. The following nasal-oral cannula was used:

Covidien Smart CapnoLine® Plus O_2, Adult/Intermediate CO_2 Oral/Nasal Sampling Set with O_2

Tubing. For their respective trials, the CCA and NC were plugged into the capnography port on a

Physio-Control LIFEPAK-15 monitor to obtain capnograms and $ETCO_2$ values. As the HPS is

meant to accurately model a variety of respiratory parameters, $ETCO_2$ and respiration rate could

not be directly manipulated to test the full range of expected values for each because this could

result in a biologically inaccurate combination of parameters. Therefore, pre-programmed patient

respiratory profiles were used for testing. For each condition, the HPS was kept in the supine

position, and CCA and NC positioning were kept constant.

Experimental Design

The following six configurations were tested: (1) NC with no CPAP mask nor O_2 flowing,

(2) CCA with no CPAP mask nor O_2 flowing, (3) NC with CPAP mask but no O_2 flowing, (4) CCA

with CPAP mask but no O_2 flowing, (5) NC with CPAP mask and O_2 flowing, and (6) CCA with

CPAP mask and O_2 flowing. Groups 1 and 2 are controls for evaluating the effects of CPAP mask

dead space (Groups 3 & 4) and CPAP therapy (Groups 5 & 6) on capnography monitored via NC

and CCA, respectively. These groups are summarized in **Table 1**. Images of the setup for Groups

1 & 3 are provided in **Fig. 1A** and **1C**, respectively. Images for Groups 2 & 4 are provided in **Fig.**

2E and **2F**, respectively. Groups 3 & 5 share the same setup as each other, as do Groups 4 & 6.

Table 1. Experimental groups used for testing on HPS.

	No CPAP mask, no O2 ("no mask")	CPAP mask, no O2 ("mask with no O2")	CPAP mask with O2 ("mask with CPAP")
NC	Group 1	Group 3	Group 5
CCA	Group 2	Group 4	Group 6

205
Groups 1-6 were each tested on three HPS standardized simulated patients: Stan D. Ardman II (Healthy

Adult Male), Grandma Smokey (COPD Patient), & Kenton Parkers (CHF & COPD Patient); these profiles

have set-point $ETCO_2$ values of 33 mmHg, 22 mmHg, and 34 mmHg, respectively.

For conditions 1-6, data were obtained from three standardized simulated patients from

the HPS system: Stan D. Ardman II (Healthy Adult Male), Grandma Smokey (COPD Patient), &

Kenton Parkers (CHF & COPD Patient). From their pre-programmed respiratory profiles, their

$ETCO_2$ targets were 33 mmHg, 22 mmHg, and 34 mmHg, respectively. The HPS continuously

adjusts modeled vital signs to remain consistent with this $ETCO_2$, as well as the rest of its pre-

programmed patient profile. As conditions 1-6 were tested for all three patients, 18 total trials were

conducted. For each trial, the $ETCO_2$ value and respiration rate were recorded from the LIFEPAK-

15 monitor's screen for 20 consecutive breaths. Simultaneously, the following modeled vital signs

were recorded from the HPS display at the exact timestamps of the same 20 breaths: respiration

rate, SpO_2, heart rate, and blood pressure. Results for the latter three vital signs are presented in

the Supplementary Information (**Fig. S4-5**). To facilitate data collection, videos were taken of both

displays, timestamps were lined up, and values were entered into a spreadsheet. Trials were

spaced one minute apart to allow for the modeled vital signs from the HPS to stabilize in response

to changes.

Statistical Analysis

For all tests, α was chosen to be 0.05. As each simulated patient had a different set-point $ETCO_2$, measured $ETCO_2$ values at each breath were normalized by dividing by their respective target $ETCO_2$. The same normalization process was done for the modeled vital signs except RR. Unlike $ETCO_2$, the HPS displayed the true RR value for each breath, so the true and measured values were used to calculate RR percent error. The average normalized $ETCO_2$, RR percent error, and modeled vital signs for breaths 1-20 in each condition were used for analysis.

Normalized $ETCO_2$ and RR percent error were associated with the following nominal independent variables: capnography monitor (NC or CCA), mask condition (no mask, mask with no O_2, and mask with CPAP), and patient (Stan D. Ardman II, Grandma Smokey, & Kenton Parkers). In accordance with the current literature,(38–40) a mixed effects model was constructed with "patient" as a random effect. Using the mixed model (multilevel linear model) feature within JMP Pro 17, the full factorial of capnography monitor, mask condition, and patient were selected as model effects; all terms containing "patient" were marked as random effects. The t-statistics were then used to obtain specific p-values.

Results

For all three patients during the experiment, it was noted that a leak was audible and could be felt by the experimenter's hands around the sides of the CPAP mask for the NC conditions when oxygen was administered (Group 5); no such leaks were noticed for the corresponding CCA condition (Group 6).

Capnography Waveform

Representative capnography waveforms are depicted in **Fig. 3**. Within each trial, waveform shape remained consistent across the 20 recorded breaths. It was noted that the waveforms obtained via the CCA appeared to consistently show more dead space compared to the NC capnograms, indicated by the waveform not fully returning to 0 mmHg during each inhalation. This was most noticeable in the "no mask" and "mask with no O_2" conditions. These same capnograms appeared to have increased α- and β-angles compared to those from the NC, with bilateral blunting of the waveforms.

Figure 3. Representative capnography waveforms across all experimental conditions. Capnography monitor and mask condition are labeled. Waveforms remained consistent within each trial for all trials. A small increase in baseline $ETCO_2$ (indicating dead space) is present for "mask with no O_2"; "mask with CPAP" waveforms have diminished magnitudes and increased β-angles. Images presented are from the "Grandma Smokey" (COPD Patient) simulated patient profile.

Across both the NC and CCA trials, waveform shape remained similar when transitioning from the "no mask" to the "mask with no O_2" condition, but a small increase in dead space was noted. Note that the CPAP setup allowed for exhaled gas to escape through a valve near the PEEP regulator when oxygen was not flowing, reducing CO_2 rebreathing; the high flow rate during CPAP forces this valve closed to prevent leaks while administering the therapy. The "mask with CPAP" waveform consistently had a lower magnitude and sharper peak compared to the "no mask" and "mask with no O_2" conditions. Specifically, the expiratory upstroke (phase II) appeared relatively unaffected, but the alveolar plateau (phase III) and inspiratory downstroke (phase IV/0) were severely blunted, with β-angles appearing to be around 180 degrees. These morphological changes were present when administering CPAP in all three patients. There were no noticeable consistent differences between NC and CCA waveforms when CPAP was being administered.

Effects on End-Tidal CO2

Box plots of "$ETCO_2$ normalized to patient" compared against "capnography monitor" and

"mask condition," as well as against each of these variables individually, are depicted in **Fig. 4.**

The same plots for respiration rate percent error are shown in **Fig. 5.** Capnography monitor was

not found to significantly affect normalized $ETCO_2$ (NC: 1.005, CCA: 0.897; $p = 0.25$) nor RR error

(NC: 9.423%, CCA: 0.690%; $p = 0.40$), indicating no difference between $ETCO_2$ and RR values

obtained from a conventional NC versus the CCA device proposed here. The interaction between

mask condition and capnography monitor was also found to have no significant effect on

normalized $ETCO_2$ ($p = 0.69$), but mask condition alone did have a significant effect ($p = 0.0308$).

Specific model parameter t-statistics revealed that the "mask with CPAP" normalized $ETCO_2$ was

significantly less than that of the "no mask" condition (0.810 vs. 0.983, respectively; $p = 0.0145$);

moreover, the "mask with no O_2" normalized $ETCO_2$ was significantly greater than that of the "no

mask" condition (1.060 vs. 0.983, respectively; $p = 0.0328$).

Figure 4. End-tidal CO$_2$ (ETCO$_2$) normalized to target among all conditions (A), by capnography

monitor (B), and by mask condition (C). No differences were found for $ETCO_2$ measured via NC versus

CCA. Application of CPAP mask without O_2 increased $ETCO_2$, and CPAP decreased $ETCO_2$. * indicates p

< 0.05 (p-values obtained from t-statistic from mixed/multilevel-linear model). Boxplots reflect data prior to

taking 20-breath averages.

Effects on Respiration Rate

RR error was 0.955% for "no mask", 0.537% for "mask with no O_2, and 13.677% for "mask

with CPAP"; mask condition and the interaction between mask condition and capnography

monitor were both found to have no significant effect on RR percent error ($p = 0.37$ & 0.44,

respectively). A single outlier caused the high RR error for "mask with CPAP" and "NC" (13.677%

and 9.423%, respectively); for the Group 5 (NC; mask with CPAP) condition for the patient

"Kenton Parkers" (CHF & COPD Patient), it was noted that an artifact on the capnography

waveform caused the LIFEPAK-15 monitor to double the measured respiration rate. This greatly

increased the mean and variance in the Group 5 data, but none of the fixed effects were found to

significantly influence RR percent error—likely as this artifact was not observed in the other

simulated patients or trials.

Figure 5. Normalized respiration rate (RR) percent error among all conditions (A), by capnography

monitor (B), and by mask condition (C). No significant differences were found in RR percent error

between any of the conditions; a single trial (Group in "Kenton Parkers") caused the extreme outliers visible

for NC and CCA. * indicates $p < 0.05$ (p-values obtained from t-statistic from mixed/multilevel-linear model).

Boxplots reflect data prior to taking 20-breath averages.

Discussion

Recall that this study was primarily concerned with elucidating any effects caused by mask

condition (no mask, mask with no O_2, and mask with CPAP) or capnography monitor (NC or CCA)

on capnogram shape, $ETCO_2$ values, and respiration rate.

Capnography Waveform

The main difference between the NC and CCA waveforms was the observed increase in

dead space—indicated by the capnogram not returning to baseline during inhalation—and altered

morphology when using the CCA. This could be due to CO_2 accumulating in the sampling line

and not being fully able to escape; however, the measured $ETCO_2$ value did not trend upward

and was stable throughout all trials, meaning exhalations did escape to some extent. Further

testing will be needed to determine which component of the CCA's design caused this artifact. A

Computational Fluid Dynamics (CFD) model could be helpful in analyzing differences in oxygen

flow through the NC versus the CCA during CPAP. However, the CCA is only meant to be used

during CPAP, and it produced nearly identical waveforms to the NC in the CPAP trials. Thus, the

altered morphology of the CCA waveforms in the "no mask" and "mask with no O_2" conditions

compared to the corresponding NC waveforms has little impact in context. Similarly, the slight

increase in dead space and $ETCO_2$ value noted upon mask placement did not significantly alter

waveform shape and is consistent with a 2017 study by Phillips et al. that showed that using an

NC sampler placed beneath a standard oxygen mask causes an increase in $ETCO_2$ due to

rebreathing.(41) The fact that CPAP consistently blunted the capnograms from both the NC and

CCA, though, is more concerning.

In addition to $ETCO_2$ value, capnogram morphology is critical for identifying possible

causes of breathing difficulties as well as response to therapy. Typically, the slope of the phase

III alveolar plateau is an indirect indicator of V/Q status in the lungs.(21) A prolonged phase II with

an increase in α-angle suggests bronchospasm or airway obstruction; an increased β-angle might

indicate rebreathing.(21) Conclusions such as these based on capnogram morphology cannot be

made during CPAP, as it is unknown if they will still be visible on the waveform. Thus, prehospital

medical providers cannot rely on their current understanding of waveform morphology to assess

a patient's breathing during CPAP. Additional research will be needed to investigate ways of

interpreting differences in waveform shape during CPAP between healthy patients and those with

various respiratory conditions.

Capnography Sampler Effect on $ETCO_2$ and Respiration Rate

Overall, no differences were found between $ETCO_2$ and RR percent error when measuring

capnography via a traditional nasal-oral cannula (NC) or the novel CPAP-Capnography Adapter

(CCA). The observation that a leak between the face and mask was present during CPAP in all

NC trials and absent in all CCA trials indicates that the CCA met its design objectives. While the

NC did have a higher RR error than the CCA (9.423% vs. 0.690%), this can be attributed to a

single trial (Group 5 for the patient "Kenton Parkers") where an artifact caused the LIFEPAK-15

to record a doubled respiration rate. This artifact was not noted in any other trials, so its effect

was not statistically significant. Additional experiments would be needed to determine if the artifact

is truly associated with the use of the NC or if it originates from some other source. Note that RR

error was consistently 0% for the vast majority of trials, so values that deviated from this were

marked as outliers in many of the conditions, resulting in several of the boxplots in **Fig. 5** showing

horizontal lines instead of a traditional box.

Mask Condition Effect on $ETCO_2$ and Respiration Rate

Administering CPAP significantly reduced the measured $ETCO_2$ (0.810) when compared

to "no mask" (0.983), which is consistent with the waveform observations. While a reduction in

$ETCO_2$ could indicate reduced $PaCO_2$, the fact that the HPS did not model $ETCO_2$ and instead

had a set target value indicates that the measured $ETCO_2$ did not accurately reflect the

mannequin's breathing profile during CPAP. Both capnography monitors recorded $ETCO_2$ values

within five percent of the HPS's target $ETCO_2$ in the control "no mask" condition (NC: 1.4% higher;

CCA: 4.89% lower), so their measurement of the partial pressure of CO_2 at the HPS's nares was

relatively accurate. Consequently, the notable decrease in $ETCO_2$ during CPAP indicates that the

CO_2 at the nares was diluted by the high oxygen flow rate (which can exceed 100 L/min).(42)

Thus, the reduction in measured $ETCO_2$ is not an artifact of the capnography samplers

themselves. As a result, this $ETCO_2$ likely would no longer correlate with $PaCO_2$ in a human

subject. Further evidence that the functionality of the capnography samplers is not compromised

by CPAP is the fact that no differences in RR percent error were found between the "no mask",

"mask with no O_2", and "mask with CPAP" conditions—indicating that the capnography samplers

obtain sufficient gas samples to record measurements during all mask conditions. Therefore,

healthcare professionals should use $ETCO_2$ values obtained during CPAP with caution, as a

decreased $ETCO_2$ value might not indicate a true decrease in a patient's $PaCO_2$.

Additional Modeled Vital Signs

Besides RR, several additional modeled vital signs were recorded from the HPS's display

during the experiment: SpO_2, heart rate (HR), and blood pressure—the latter of which was

converted to an estimated mean arterial pressure (MAP) using: MAP = $P_{systolic}/3 + 2*P_{diastolic}/2$.(43)

See **Fig. S4** for SpO_2 results, and **Fig. S5** for HR and MAP results. The magnitude of the HR and

MAP differences within each simulated subject prior to normalization was very low (+/-1 bpm, and

+/- 2 mmHg, respectively), so no meaningful conclusions were drawn from them. Statistical

standardization was performed on the 20-breath average SpO_2 from each trial. Only mask

condition was found to influence SpO_2, with SpO_2 increasing during CPAP compared to "no mask"

and "mask with no O_2" (p = 0.0110). This change aligns with the expected physiological response,

but the magnitude of the differences was very low within each subject prior to

normalization/standardization (+/- 1%). The overall lack of variation in the HPS's vital signs

throughout the experiments is due to the mannequin's adherence to the pre-programmed

simulated patient profiles. Note that the aforementioned findings regarding capnogram shape,

$ETCO_2$, and RR percent error do not depend on the HPS's response to the therapy.

Relationship with Previous Studies

In 2012, Razi et al. showed good correlation between $PaCO_2$ and $ETCO_2$ obtained

during mechanical ventilation (including CPAP) in a hospital setting. However, these patients

were intubated and monitored in a mainstream manner.(44) In 2015, Piquilloud et al. used an

NC sampler to monitor capnography in ICU patients receiving non-invasive ventilation (NIV),

and found that $ETCO_2$ was inadequate to predict both $PaCO_2$ value and variations over time.

However, they only included 11 patients in their study, and used bi-level positive airway

pressure (BiPAP) instead of CPAP.(45) A much larger study of 154 patients was published in

2021 by Uzunay et al. that showed a significant difference between $ETCO_2$ and $PaCO_2$ during

both non-invasive BiPAP and CPAP in the emergency department. However, a positive

moderate correlation was present, so the authors stated that capnography monitoring during

NIV may still be beneficial for predicting $PaCO_2$ changes in response to therapy—allowing for a

quicker decision to be made regarding switching to intubation.(28) The mainstream

capnography monitoring method they used is not compatible with prehospital CPAP nor existing

EMS cardiac monitors, though. Most recently, Sakuraya et al. showed in 2022 that $PaCO_2$ and

$ETCO_2$ correlate well during CPAP when measured via an NC in a sidestream manner, and

correlate even better when measured in a mainstream manner. Their study was conducted on

60 recently extubated ICU patients. The authors concluded that the results of previous studies

monitoring $ETCO_2$ during NIV were mixed likely due to physiological issues and shortcomings of

exhalation sample collection.(12)

None of the existing studies described changes to waveform morphology nor used a

prehospital CPAP system. Further, Sakuraya et al. is the only one that used a capnography

sampler compatible with common EMS cardiac monitors during non-invasive CPAP. All the

studies presented here assessed the correlation of $PaCO_2$ to $ETCO_2$ in human subjects, and

they achieved mixed results likely due to physiological factors and variations in methodology.

Our study complements this work by showing that—with physiological factors and variation

removed through the use of an HPS—$ETCO_2$ value and capnogram morphology are directly

compromised by CPAP itself. We did not assess $PaCO_2$; however, we show that the $ETCO_2$

value and capnogram shape should not be interpreted with current protocols. Additional

research into interpreting the value and waveform when taken during CPAP is needed.

Limitations and Future Directions

The primary limitation of this study is that it was conducted on simulated patient profiles

on an HPS. The CAE Healthcare HPS is extremely accurate at mixing respiratory gasses and

mimicking human breathing, so it is commonly used in anesthesia training.(46–49) Using an HPS

rather than human subjects allows for greater control of confounding variables, facilitates rapid

data collection, and relieves the ethical concerns (and IRB approval) of testing a novel

capnography sampler on patients in respiratory distress who are receiving CPAP. However, it is

not a perfect substitute for testing on human subjects. For example, it omits important factors

such as emotions, which are known to significantly affect respiration rate.(50) Due to this, future

controlled clinical trials might analyze $ETCO_2$, respiration rate, and other vital signs on healthy

voluntary subjects under the same six conditions used here. It would be beneficial for $PaCO_2$ to

be monitored during these trials so that the correlation between $ETCO_2$ and $PaCO_2$ could be

analyzed under the "no mask", "mask with no O2", and "mask with CPAP" conditions. A controlled

trial like this would provide far greater clarity than the existing observational studies, which have

yielded largely mixed results regarding $ETCO_2$'s correlation with $PaCO_2$ during NIV. Such

experiments are outside the scope of this article but could strengthen the results presented here.

Another factor that could be analyzed in a future publication is capnography sampling

location. This study monitored nasally with the CCA, and oro-nasally with the NC. Patients who

are candidates for CPAP often breathe through their mouths, then through their noses as their

condition improves.(32) A comparison of sampling nasally vs. orally vs. both was not conducted

due to the limitations of the HPS (the nares and mouth are connected and are not able to model

differences in breathing nasally vs. orally).

Finally, while it is evident that $ETCO_2$ and capnogram shape are significantly altered by

CPAP, this does not mean that capnography is a useless tool for patients receiving the therapy.

It would be beneficial for future studies to examine if there are consistent changes that occur to

the capnogram and $ETCO_2$ value when a patient's condition is improving. If so, then healthcare

providers could still use capnography to monitor the effectiveness of CPAP but might require

additional training on interpreting the altered waveform morphology and $ETCO_2$ value. This type

of analysis was not possible here as the HPS had an internal $PaCO_2$ set-point for each patient

profile, but investigating this in human subjects would be very informative.

Conclusions

CPAP and capnography have many overlapping indications, but combining their use in

the prehospital setting has not been well studied. Despite this, some EMS education sources

recommend using an NC for capnography during CPAP. Previous studies have investigated the

correlation of $ETCO_2$ to $PaCO_2$ during NIV in the hospital setting with conflicting results, likely due

to mixed methodologies and physiological factors. Using an HPS to standardize confounding

variables, we assessed CPAP's effect on capnogram morphology, $ETCO_2$, and respiration rate

accuracy. In addition to using a conventional NC, we introduced a novel capnography sampler

(the CCA) that overcame the NC's issue of breaking CPAP's mask-face seal. The NC and CCA

were equally accurate for measuring respiration rate, and both maintained this accuracy with and

without CPAP; the two capnography samplers also did not produce differences in $ETCO_2$

measurements. However, placing a mask without O_2 flowing on the HPS increased $ETCO_2$, and

administering CPAP decreased $ETCO_2$. As this occurred while the HPS was running a pre-

programmed respiratory profile with set-point $ETCO_2$ and $PaCO_2$, the results indicate that

measuring exhaled CO_2 is not an accurate way to reflect patient breathing during CPAP. The

capnography waveform was also compromised by CPAP, limiting its potential as a diagnostic tool.

Therefore, healthcare professionals should interpret $ETCO_2$ values and capnogram shape with

caution while administering CPAP.

Acknowledgments

Supporting Information

Figure S1. Engineering sketches of Capnography-CPAP Adapter (CCA). Multiple isometric, side, top,

and bottom views are depicted for both the elbow adapter and nasal sampler portions. All necessary

dimensions for replication are labeled (in mm and degrees); sharp edges were filleted.

Figure S2. SpO_2 standardized to patient among all conditions (A), by capnography monitor (B), and

by mask condition (C). Capnography monitor did not affect SpO_2; applying CPAP significantly increased

SpO_2 compared to "no mask". Mixed model approach did not converge, so SpO_2 was standardized to

remove the random effect of "patient". Then, MANOVA was run; no significant interactions were found, so

p-values were obtained from unpaired two-tailed t-tests. * indicates $p < 0.05$. Boxplots reflect data prior to

taking 20-breath averages.

Figure S3. Normalized heart rate (HR) and mean arterial pulse (MAP) among all conditions (HR: A;

MAP: D), by capnography monitor (HR: B; MAP: E), and by mask condition (HR: C; MAP: F). HR was

higher for CCA trials compared to the NC; MAP was reduced in the CPAP trials compared to "no mask".

Note that the observed differences, prior to normalization, were +/- 1 bpm and +/- 2 mmHg for HR and

MAP, respectively. * indicates $p < 0.05$ (p-values obtained from t-statistic from mixed/multilevel-linear

model). Boxplots reflect data prior to taking 20-breath averages.
