ABSTRACT

PURPOSE: Gamma delta T-cell receptor-positive acute lymphoblastic leukemia (γδ T-ALL) is a high-risk but poorly characterized disease.

METHODS: We studied clinical features of 200 pediatric γδ T-ALL, and compared the prognosis of 93 cases to 1,067 protocol-matched non-γδ T-ALL. Genomic features were defined by transcriptome and genome sequencing. Experimental modeling was used to examine the mechanistic impacts of genomic alterations. Therapeutic vulnerabilities were identified by high throughput drug screening of cell lines and xenografts.

RESULTS: γδ T-ALL in children under three was extremely high-risk with 5-year event-free survival (33% v. 70% [age 3-<10] and 73% [age ≥10], P=9.5 x 10^-5) and 5-year overall survival (49% v. 78% [age 3-<10] and 81% [age ≥10], P=0.002), differences not observed in non-γδ T-ALL. γδ T-ALL in this age group was enriched for genomic alterations activating LMO2 activation and inactivating STAG2 inactivation (STAG2/LMO2). Mechanistically, we show that inactivation of STAG2 profoundly perturbs chromatin organization by altering enhancer-promoter looping resulting in deregulation of gene expression associated with T-cell differentiation. Drug screening showed resistance to prednisolone, consistent with clinical slow treatment response, but identified a vulnerability in DNA repair pathways arising from STAG2 inactivation, which was efficaciously targeted by Poly(ADP-ribose) polymerase (PARP) inhibition, with synergism with HDAC inhibitors. Ex-vivo drug screening on PDX cells validated the efficacy of PARP inhibitors as well as other potential targets including nelarabine.

CONCLUSION: γδ T-ALL in children under the age of three is extremely high-risk and enriched for STAG2/LMO2 ALL. STAG2 loss perturbs chromatin conformation and differentiation, and STAG2/LMO2 ALL is sensitive to PARP inhibition. These data provide a diagnostic and therapeutic framework for pediatric γδ T-ALL.
INTRODUCTION

The outcome of T-cell acute lymphoblastic leukemia (T-ALL) has improved with recent changes in therapeutic strategy including the incorporation of new drugs such as nelarabine as well as minimal residual disease (MRD)-based risk adaptation, however outcomes remain inferior to B-ALL. One group of high-risk T-ALL that is potentially associated with higher rates of refractory disease and poor prognosis is gamma delta (γδ) T-ALL, which expresses the γδ T-cell receptor (TCR) and accounts for 10% of T-ALL. Yet, the clinical features and prognostic significance of γδ T-ALL have been only examined in small cohorts.

Genomic analyses have identified multiple new subtypes and drivers of B-ALL, and have transformed the approach to diagnosis, risk classification, and for some subtypes, therapeutic targeting. Recent studies have examined the genomic landscape of T-ALL using whole exome sequencing (WES) and whole transcriptome sequencing (RNAseq), and have defined several T-ALL subtypes arising from dysregulated oncogene expression. However, these studies included few documented cases of γδ T-ALL, and the genomic basis of this form of leukemia remains elusive. Moreover, these genomic studies have demonstrated the limitations of non-whole genome sequencing (WGS) studies of T-ALL, in which oncogene-deregulating genomic alterations commonly involve non-coding regions of the genome that are not detected by RNAseq or WES, and require WGS and chromatin profiling approaches such as HiChIP to fully elucidate driver genomic alterations.

Thus, limited studies have explored the clinical and genomic characteristics of γδ T-ALL. In this study, we sought to conduct a comprehensive analysis of this entity, to identify outcome determinants, and to explore the therapeutic potential for better classification and improved outcomes.
METHODS

Study Design

Data from all patients with T-ALL expressing γδ TCR up to 25 years of age enrolled in clinical trials and diagnosed from January 1, 2000, through December 31, 2018, were retrospectively collected from 13 cooperative study groups (n=200, Appendix Table A1). Data from patients with non-γδ T-ALL (n=1,067) enrolled on the same protocols (DCOG-ALL10,14 AIEOP-BFM ALL2000,4 EORTC 58951,15 SJCRH-T15/T1616,17) were collected for comparison analysis (Fig 1A). Only the protocol-matched patients from these four groups were used for the outcome analyses; for the analyses of clinical features, we used all 200 γδ T-ALL data. All clinical trials were approved by institutional review boards or ethics committees. This study was approved by the Institutional Review Board of St. Jude Children’s Research Hospital.

Terminology and Outcomes

The following definitions were used to analyze clinical features according to an international consensus of the Ponte-di-Legno Consortium.18 The definition of the time points at the end of induction (EOI) and consolidation (EOC) was approximately four weeks and 7-12 weeks (day 42/46 for SJCRH-T15/T16) from the start of treatment, respectively (Appendix Table A1). Complete remission (CR) was defined when bone marrow (BM) showed M1 cytomorphology and/or MRD <1% without evidence of extramedullary disease at EOC. When MRD data were available, MRD results were preferentially used to define CR. MRD was measured by PCR and/or flow cytometry depending on the study. Failure to achieve CR was defined as a treatment failure event on EOC assessment day. Event-free survival (EFS) was defined as the time from the start of treatment to any of the first events including the death of any time, treatment failure, relapse, second malignancy, or last follow-up date for those who were event-free. Overall survival (OS) was defined as the time from the start of treatment to death from any cause or last follow-up date.
Patient samples, sequencing, gene-edited models, and drug screening

Details for the process of primary materials, WGS, RNAseq, HiChIP, chromatin immunoprecipitation sequencing (ChIP-seq), and methods for cell culture, generation of CRISPR/Cas9-based gene-edited models, and drug screening are described in the Data Supplement, Supplementary Methods.

Statistical Analysis

Statistical analyses were performed using R v.4.2.2 software. Categorical variables were analyzed using the Chi-square test. The two-sided Wilcoxon rank-sum test was used to compare the mean values of different groups. Two-sided log-rank tests were used for survival analyses. For univariate and multivariate analyses of prognostic factors, the Cox proportional hazards regression model was used.

RESULTS

Identification of a subset of high-risk γδ T-ALL in the very young

A total of 200 cases of γδ T-ALL patients were assembled through a consortium of 13 ALL study groups (Appendix Table A1). From the analysis of those treated in the same clinical trials, the frequency of γδ T-ALL was 8.0% of T-ALL (n=93 and 1,067 for γδ T-ALL and non-γδ T-ALL, respectively, Fig 1A), and γδ T-ALL patients exhibited significantly inferior 5-year EFS (65% v. 76%, \(P=0.01\)) and OS (77% v. 83%, \(P=0.048\)) compared to non-γδ T-ALL patients (Fig 1B). In comparison with non-γδ T-ALL, γδ T-ALL patients were characterized by younger age at diagnosis (\(P=0.01\)), higher white blood cell (WBC) at diagnosis (\(P=0.02\)), less frequent mediastinal mass (\(P=9.1 \times 10^{-5}\)), and a more common mature T immunophenotype (surface (s)CD3+, CD1a-, \(P=1.3 \times 10^{-15}\), Table 1, and Appendix Table A2). MRD measurements were available for 90, 121, and 131 patients at day 15, EOI, and EOC, respectively. γδ T-ALL patients exhibited a higher rate of poor prednisone response (\(P=0.0008\)), MRD ≥1% (≥10^{-2}) at day 15 (\(P=4.3 \times 10^{-7}\)), at EOI (\(P=6.4 \times 10^{-8}\)) and at EOC (\(P=6.1 \times 10^{-8}\), Table 1, and Appendix Table...
A2), suggesting slow treatment response and chemoresistance leading to treatment failure. Accordingly, more \( \gamma \delta \) T-ALL patients underwent hematopoietic stem cell transplantation (\( P=6.4 \times 10^{-5} \)) and died from primary disease (16.8% v. 11.2%) and toxicity during treatment compared to non-\( \gamma \delta \) T-ALL patients (7.6% v. 4.0%, \( P=0.0004 \), Table 1, and Appendix Table A2). The cumulative incidence of relapse (Appendix Fig A1A) and OS after relapse and treatment failure in \( \gamma \delta \) T-ALL were similar to that of non-\( \gamma \delta \) T-ALL (Appendix Fig A1B,C). Importantly, there was a significant difference in the site of relapse; almost all relapses of \( \gamma \delta \) T-ALL were isolated BM relapses (91.3% v. 50.0%), while central nervous system (CNS, isolated CNS and combined CNS/BM) was more commonly involved in non-\( \gamma \delta \) T-ALL (4.3% v. 41.6%, \( P=0.003 \), Table 1, and Appendix Fig A1D). No difference was observed in CNS involvement at diagnosis between \( \gamma \delta \) and non-\( \gamma \delta \) T-ALL (Appendix Table A2).

Strikingly, \( \gamma \delta \) T-ALL diagnosed before three years of age exhibited markedly inferior EFS compared to those diagnosed in older children (33% v. 70% [age 3-<10] and 73% [age \( \geq \)10], \( P=9.5 \times 10^{-5} \)) and OS (49% v. 78% [age 3-<10] and 81% [age \( \geq \)10], \( P=0.002 \)), a difference that was not observed in non-\( \gamma \delta \) T-ALL (EFS; 72% v. 80% [age 3-<10] and 76% [age \( \geq \)10], OS; 80% v. 86% [age 3-<10] and 81% [age \( \geq \)10]) (Fig 1C, Table 1, and Appendix Table A2). Eleven out of 24 \( \gamma \delta \) T-ALL patients under three years old died from primary disease or toxicity. In addition, \( \gamma \delta \) T-ALL with MRD \( \geq 1\% \) at EOI showed poor EFS (51% v. 96% [below 0.01%] and 91% [0.01%–1%], \( P=7.6 \times 10^{-7} \)) and most were not salvaged (OS, 66% v. 96% [below 0.01%] and 91% [0.01%–1%], \( P=0.001 \), Fig 1D and Table 1). Positivity (\( \geq 0.01\% \)) of MRD at EOC also predicted poor EFS (41% v. 88%, \( P=3.0 \times 10^{-10} \)) and OS (66% v. 88%, \( P=0.001 \), Fig 1E, Table 1, and Appendix Fig A1E). Forty-four out of 53 (83%) patients with MRD \( \geq 1\% \) at EOI remained MRD positive at EOC and 34% (n=18) of them died (Appendix Fig A1F). In a multivariable analysis, age under three was associated with worse EFS and OS, though MRD levels at EOI (\( \geq 1\% \)) and EOC (\( \geq 0.01\% \)) remained important prognostic factors in MRD-directed protocols.
The use of MRD-stratified protocols did not improve the outcome of γδ T-ALL (Appendix Table A2 and Appendix Fig A1G). Thus, clinical data identified two high-risk groups in γδ T-ALL - those under three years of age and those with MRD ≥1% at EOI – that required alternative therapy, rather than intensification with conventional treatment.

Enrichment of the STAG2/LMO2 subtype in high-risk γδ T-ALL in the young

To determine the genetic basis of γδ T-ALL, WGS (n=47) and RNAseq (n=68) were performed, including 15 additional γδ T-ALL samples (Appendix Tables A4–A7). We combined analysis of these samples with 1,076 T-ALL cases whose TCR status at diagnosis was not available (Children's Oncology Group AALL0434 study2.19). Gene expression profiling revealed that γδ T-ALL cases were classified by leukemia-initiating events and maturation stages (Fig 2A, Appendix Fig A2, and Appendix Table A8). γδ T-ALL was enriched for several subtypes including LMO2 γδ-like, T-ALL with recurrent chromosome gains (Chr gains), STAG2/LMO2, TLX3-rearrangement, and PICALM::MLLT10 (Fig 2B). Each of these subtypes except for STAG2/LMO2 is described in Data Supplement, Supplementary Results, Appendix Fig A3,4, and Appendix Table A9.

STAG2/LMO2 is a subtype enriched in γδ T-ALL that has a distinct expression profile (7.9% for γδ T-ALL v. 0.9% in non-γδ T-ALL, Fig 2A,B). All STAG2/LMO2 cases had dual-hit alterations targeting LMO2 and STAG2 (Fig 2C). All STAG2/LMO2 γδ cases were diagnosed before the age of three, including infancy, a pattern of age at diagnosis not observed in other γδ T-ALL subtypes (Fig 2D).

The clinical outcomes of γδ T-ALL exhibited significant variation depending on the genomic subtype. The Chr gains and TLX3-rearranged subtypes had excellent OS (Fig 2E). In contrast, the STAG2/LMO2, LMO2 γδ-like, and KMT2A-rearranged subtypes had poor EFS, and notably, these subtypes included all γδ T-ALL patients diagnosed under the age of three (Fig 2F).
Among these three γδ T-ALL subtypes, STAG2/LMO2 was predominantly related to young onset under three, indicating the overlap of high-risk groups in γδ T-ALL (Fig 2F). Indeed, three out of five STAG2/LMO2 cases succumbed to death by the primary disease. Thus, integrated clinico-genomic analyses demonstrated that the STAG2/LMO2 subtype is enriched in children diagnosed with T-ALL under the age of three and the γδ immunophenotype, who had dismal outcomes.

Dual hit genomic drivers in STAG2/LMO2 T-ALL

To further elucidate the biology of STAG2/LMO2 subtype, we collected and analyzed 18 additional STAG2/LMO2 cases including non-γδ T-ALL (total 24 cases, Appendix Table A10). All but 2 (both from additional cases and diagnosed before 4 years of age) were diagnosed before age three and included five infant T-ALL cases (Fig 3A). Unlike the general male sex predominance in T-ALL, female sex was more common (58%) in STAG2/LMO2 T-ALL.

Dual-hit alterations at the LMO2 and STAG2 loci were identified in all 20 cases with WGS data. Most commonly, these included LMO2::STAG2 rearrangements (n=15, 75%); alternatively, LMO2 enhancer single nucleotide variants or rearrangements to TCR loci that resulted in aberrant LMO2 expression, were present with concurrent STAG2 alterations leading to premature truncation (Fig 3A,B and Appendix Table A10). LMO2::STAG2 does not generate a fusion chimera, thus these rearrangements could not be identified in cases lacking WGS. In most cases, breakpoints were detected upstream of LMO2 and within the introns of STAG2 (Fig 3C, Data supplement, Supplementary Fig S1, and Appendix Table A10). H3K27ac HiChIP to integrate enhancer profiling with chromatin looping was performed in the STAG2/LMO2 MOLT-14 cell line. This showed abnormal looping between STAG2 promoter and LMO2 promoter/enhancers, indicating the induction of LMO2 expression at the cost of STAG2 expression (Fig 3D and Appendix Fig A5A,B). All cases had NOTCH1 activating alterations,
but few additional alterations, suggesting that \textit{LMO2} deregulation, \textit{STAG2} inactivation, and \textit{NOTCH1} pathway activation are necessary and sufficient drivers of leukemogenesis.

\textit{STAG2/LMO2} cases exhibited up-regulation of LIN28/let-7 pathway genes, which are expressed in fetal hematopoietic stem cells (HSCs) and silenced after birth and following HSC differentiation\textsuperscript{20} (\textbf{Fig 3E}, \textbf{Appendix Fig A5C–E}, and \textbf{Appendix Table A11}). \textit{HBE1}, \textit{GATA1} and \textit{GATA2}, key genes for early-stage hematopoiesis, were also highly expressed (\textbf{Fig 3E}), suggesting a fetal HSC origin of \textit{STAG2/LMO2} ALL. Pathway analysis using the up-regulated genes in \textit{STAG2/LMO2} revealed the enrichment of pathways related to stem cell proliferation (\textbf{Fig 3F}). Furthermore, gene-set enrichment analysis revealed up-regulation of \textit{MYC} and \textit{GATA1} target pathways (\textbf{Fig 3G} and \textbf{Appendix Table A12}).

\textbf{STAG2 inactivation in T-ALL induces epigenomic deregulation}

Although dual-hit alterations of \textit{LMO2} and \textit{STAG2} are unique features of the \textit{STAG2/LMO2} subtype, aberrant expression and/or alterations of \textit{LMO2} alterations are frequently observed in other subtypes of T-ALL, especially those with deregulation of \textit{TAL1}. However, \textit{STAG2} alterations are specific for \textit{STAG2/LMO2} T-ALL, and \textit{STAG2} inactivation may drive the pathogenesis and gene expression profiles of this subtype. \textit{STAG2} is a member of the cohesin complex which has a critical role in the maintenance of enhancer-promoter short loops.\textsuperscript{21} Therefore, loss of \textit{STAG2} alters CTCF-anchored loop extrusion and rewrites enhancer-promoter loops.\textsuperscript{22-24} Accordingly, chromatin loop size defined by H3K27ac HiChIP (generally representing enhancer-promoter loops) was highest in \textit{STAG2/LMO2} cell lines compared to normal thymocytes and T-ALL cases, with the exception of DND-41, a \textit{TLX3}-rearranged T-ALL cell line with \textit{CTCF} alteration (\textbf{Fig 4A}).

To further explore the effect of \textit{STAG2} inactivation in T-ALL, we developed two gene-edited cell line models: (1) empty vector (EV) or \textit{STAG2} transduced MOLT-14 (\textit{STAG2/LMO2}),
and (2) STAG2 knockout PF382 (LMO2-activating mutation; Fig 4B, Data supplement, Supplementary Results, and Appendix Fig A6,A7). Comparison of MOLT14-EV (STAG2 inactivation) and MOLT14-STAG2 (STAG2 restoration) in H3K27ac binding peaks and corresponding gene expression levels revealed genes regulated by STAG2 expression, including CD34, ID1 and ID2 (Fig 4C,D and Appendix Table A13). Pathway analysis (Appendix Fig A6D) suggested differentiation arrest induced by STAG2 inactivation.

We next examined the effects of STAG2 inactivation by using PF382 parental and STAG2 knockout lines. STAG2 inactivation resulted in de-regulation of genes associated with T-cell differentiation, cell cycle, and polyamine metabolism in addition to STAG1 (Fig 4E,F, Appendix Fig A6E and Appendix Table A14). Comparison of differentially expressed genes between PF382 STAG2 knockout v. parental cells, and STAG2/LMO2 T-ALL v. other T-ALL cases revealed 269 up-regulated and 163 down-regulated genes in common (Fig 4G, Appendix Fig A6F and Appendix Table A15). STAG2 binding in PF382 cells was partly compensated by STAG1 after STAG2 inactivation, consistent with up-regulation of STAG1 expression following STAG2 loss (Fig 4H and Appendix Fig A6H,A7). Differential peaks of H3K27 acetylation and corresponding gene expression changes between PF382 parental and STAG2 knockout cells included T-cell differentiation-related genes as seen in the MOLT-14 model (Fig 4I and Appendix Table A16). Thus, STAG2 inactivation drives perturbation of gene expression in STAG2/LMO2 T-ALL, and T-cell differentiation arrest by deregulating chromatin conformation.

**Therapeutic targeting of STAG2/LMO2 T-ALL**

To identify potential new therapeutic approaches for STAG2/LMO2 T-ALL, we performed drug-response screening for 2,050 compounds in two LMO2::STAG2 T-ALL cell lines: MOLT-14 (γδ T-ALL) and PER-117 (non-γδ T-ALL; Appendix Table A17). 138 compounds were active in
both cell lines at 10 µM single-dose screening, and in subsequent dose-response testing, 85 exhibited moderate to high efficacy (EC$_{50}$ <1 µM) in both cell lines (Fig 5A and Appendix Table A18). Multiple histone deacetylase (HDAC), topoisomerase, and bromodomain (BRD) inhibitors showed efficacy (Appendix Fig A8A). Notably, inhibitors of the deregulated LIN28B and NTRK1 genes in the STAG2/LMO2 subtype (Fig 3E), were ineffective (Appendix Fig A8B–E), suggesting that deregulated expression of these genes is reflective of cell stage or state but is not oncogenic or a therapeutic vulnerability.

Recent studies have reported the efficacy of Poly(ADP-ribose) polymerase (PARP) inhibitors in STAG2-inactivated cancers, including glioblastoma, myelodysplastic syndromes (MDS), and acute myeloid leukemia (AML) due to stalled replication forks and increased double-strand DNA breaks$^{25-28}$ (DDB, Fig 5B). The PARP inhibitor talazoparib was one of the most effective compounds in the STAG2/LMO2, but not STAG2 wild-type T-ALL cell lines (Fig 5C). Moreover, synergism with a low dose HDAC inhibitor,$^{29,30}$ vorinostat (0.1 and 0.2 µM), was observed in STAG2/LMO2 lines, but not in STAG2 wild-type lines (Fig 5D and Appendix Fig A8F,G).

Finally, we validated the drug efficacy on STAG2/LMO2 subtype by using patient-derived xenografts (PDX) cells from γδ TCR positive T-ALL exposed to a panel of 26 drugs including conventional chemotherapeutics and pathway-directed agents$^{31}$ (Appendix Table A19). This showed resistance to prednisolone that is consistent with slow treatment response in patients (Fig 5E,F). Effective drugs included PARP (talazoparib, olaparib), HDAC (vorinostat), BCL2 (venetoclax, navitoclax) and, BRD (JQ1) inhibitors, nelarabine and L-asparaginase, supporting the results of cell line screening (Fig 5E,F).
DISCUSSION

Despite the recent improvement of outcomes in pediatric T-ALL,\(^1\)\(^-\)\(^3\) \(\gamma\delta\) T-ALL continues to pose a significant high-risk challenge. Due to the rarity of this disease and the lack of routine \(\alpha\beta/\gamma\delta\) TCR tests by flow cytometry at diagnosis in some clinical trials, comprehensive clinical and genomic analyses of \(\gamma\delta\) T-ALL have been lacking. To address this, we established a multinational consortium that assembled a cohort of 200 pediatric \(\gamma\delta\) T-ALL patients across various study groups. These patients were compared with a group of 1,067 protocol-matched non-\(\gamma\delta\) T-ALL patients, shedding light on several distinct features of \(\gamma\delta\) T-ALL. One pivotal characteristic was the sluggish response to treatment and resistance to current therapeutic approaches. This resistance often necessitated intensified treatment regimens, including transplantation, and resulted in a high rate of mortality from both primary disease and treatment-related toxicity. Additionally, predominant BM relapses were observed, though CNS-related relapses are common in non-\(\gamma\delta\) T-ALL. Notably, these features were especially pronounced in patients under three years old or those with MRD \(\geq 1\%\) at EOI. These patient groups are considered extremely high-risk in the context of \(\gamma\delta\) T-ALL, necessitating alternative therapeutic strategies rather than treatment intensification. In contrast, other \(\gamma\delta\) T-ALL cases showed favorable outcomes and may continue to benefit from the current treatment strategy.

Our genomic analysis revealed that the \(STAG2/LMO2\) subtype was enriched in high-risk \(\gamma\delta\) T-ALL. The \(STAG2/LMO2\) subtype was predominantly associated with a younger age group, primarily affecting children under the age of three including infants. This subtype exhibits a distinct expression profile with dual-hit alterations of \(LMO2\) and \(STAG2\). The young onset of \(STAG2/LMO2\) T-ALL, up-regulation of \(HBE1\) (the hemoglobin subunit expressed in the embryonic yolk sac), and the LIN28/let-7 pathway (whose expression in normal HSCs is limited to the fetal period, as well as \(\gamma\delta\) thymocytes\(^{20,32}\)), may suggest a fetal hematopoietic origin. In addition, \(Lin28b\) expression was the highest in \(\gamma\delta\) T-cells among mouse thymocyte subsets at
birth, and ectopic Lin28b expression in adult mouse HSCs promoted γδ T-cell development, supporting the enrichment of STAG2/LMO2 ALL in γδ T-ALL resulting from the activation of LIN28/let-7 pathway in leukemogenesis.

Our analyses suggest that many of the distinct biologic features of STAG2/LMO2 ALL may be attributed to inactivation of STAG2, considering the frequent activation of LMO2 and NOTCH1 across the landscape of T-ALL. STAG1 and STAG2 constitute a cohesin complex that is crucial in the maintenance of three-dimensional genome architecture. Although partly redundant, these paralogues have distinct roles in chromatin accessibility and organization. STAG1 mediates demarcation of topologically associating domains (TAD) with CTCF, whereas STAG2 patterns H3K27ac and regulates cell-type specific transcription through short loops within TAD. The function of STAG2-cohesin is more prominent in generating loops between enhancers and promoters. Therefore, STAG2 inactivation alters enhancer-promoter looping, resulting in deregulation of transcription. Larger H3K27ac-based loops in STAG2/LMO2 ALL and changes of H3K27ac peaks and expression at the regions of T-cell differentiation-related genes in our STAG2 gene-edited models may suggest involvement of STAG2 inactivation in leukemogenesis by introducing differentiation arrest.

Inactivation of STAG2 may generate an “Achilles heel” in STAG2/LMO2 ALL by increasing stalled and collapsed replication forks, leading to DDB. PARP inhibitors generate DDB by blocking DNA repair pathways and might accelerate the accumulation of DDB in STAG2/LMO2 ALL, resulting in cell death, as seen in MDS/AML with alterations of STAG2. Talazoparib is a potent PARP inhibitor due to its strong PARP trapping, and was one of the most potent of 2,050 compounds in inhibiting STAG2/LMO2 ALL cell proliferation, and its effect was specific to the STAG2/LMO2 ALL. However, unlike BRCA-deficient cells, STAG2/LMO2 ALL does not result in synthetic lethality by inhibition of single-strand DNA repair pathways through PARP inhibitors, because homologous recombination is not affected in
STAG2/LMO2 ALL, and thus the sensitivity of PARP inhibitors may depend on the strength of PARP trapping. Therefore, exploring combinatorial therapy is warranted to most effectively treat STAG2/LMO2 ALL. HDAC inhibitors are attractive due to their observed efficacy, and their ability to inhibit double-strand DNA repair pathways via promoting PARP trapping through PARP1 acetylation.  

In conclusion, early onset γδ T-ALL observed in infants and very young children represents an exceptionally high-risk group of leukemia, prominently associated with STAG2/LMO2 subtype. STAG2 inactivation perturbs chromatin organization and hematopoietic differentiation, whereas also rendering DNA repair pathways vulnerable. The insights gained from our findings hold the potential to inform more precise refined risk stratification at diagnosis and pave the way for innovative therapeutic strategies that are needed to cure this form of leukemia.

Figure Legends

Figure 1 Study cohort and outcome of γδ and non-γδ T-ALL. A, CONSORT diagram. B, γδ T-ALL showed significantly worse overall survival (OS) and event-free survival (EFS) compared to non-γδ T-ALL. C, Poor OS and EFS of γδ T-ALL for children under three years of age (top panels); outcomes of non-γδ T-ALL (dotted line) did not vary by age (bottom panels). D, γδ T-ALL patients with MRD≥10⁻² (1%) at EOI exhibited significantly worse OS and EFS than those with MRD<10⁻². E, γδ T-ALL patients with positive MRD (≥10⁻⁴) at the end of consolidation (EOC) had inferior outcomes to those with undetectable MRD. The P values were calculated using the log-rank test.
Figure 2 The intersection of genomics and clinical features of γδ T-ALL. A, UMAP plot of gene expression analysis for 68 cases of γδ T-ALL (large bold circles) layered on the reference T-ALL cohort (n=1,076, small circles). B, Frequency of each genomic subtype in the γδ T-ALL cohort (n=76), non-γδ T-ALL cases from Total 15/16 of St. Jude Children’s Research Hospital (n=113), and AALL0434 cohorts (no TCR data at diagnosis was available, n=1,076). C, Heatmap showing the mutational landscape, the expression level of selected subtype defining genes, and clinical parameters of the 76 cases of γδ T-ALL. Black color in expression indicates no data. D, Age distribution of each genomic subtype in γδ T-ALL cases (n = 76). E, Event-free survival (EFS) and overall survival (OS) in each genomic subtype. The P value was calculated using the log-rank test. F, Correlation of clinical features and genomic subtypes.
Figure 3 The genomics of STAG2/LMO2 T-ALL. A, Heatmap showing the mutational landscape and clinical parameters of the 24 cases of STAG2/LMO2 T-ALL, including 6 cases of γδ T-ALL, 5 of non-γδ T-ALL, and 13 lacking TCR status at diagnosis (n=13). B, Example of variant alterations of STAG2 inactivation. One case harbored a 13 bp indel alteration in intron 3 of STAG2, resulting in a putative exon, aberrant splicing and early STAG2 truncation. Sashimi plots shows the splicing between STAG2 exon 2 and exon 4. Intron indel alterations (orange) deregulate splicing of this region, generating a putative exon between exon 3 and 4 with early truncation. C, Breakpoints of LMO2::STAG2 translocation are shown in red bar. D, H3K27ac HiChIP on MOLT-14 cell line with LMO2::STAG2 is shown. Data was aligned on a custom reference that mimics chromosome 11 (orange) and X (cyan) translocation in MOLT-14. The top heat map represents raw interaction, and HiChIP and RNAseq coverage tracks are shown in the middle and the bottom, respectively. Significant H3K27ac-anchored interactions (FDR<0.01) are shown as arcs. Interactions between the STAG2 promoter and the LMO2 gene are shown in red. E, Differentially expressed genes in STAG2/LMO2 cases (n=24) compared with other T-ALL (n=1,120) are shown in the volcano plot. LIN28/let-7 pathway genes are colored orange. Cohesin complex genes (STAG1 and STAG2) are colored green. F, Pathway analysis (GO Biological Process) using up-regulated genes (n=78, adjusted P<0.01 and fold change >2) in STAG2/LMO2 compared to other T-ALL cases. G, Up-regulated pathways in STAG2/LMO2 subtype compared to other T-ALL cases analyzed by gene set enrichment analysis.
Figure 4 Effects of STAG2 inactivation in T-ALL cell line models. A, Chromatin loop size defined by H3K27ac HiChIP for representative T-ALL subtypes (blue and orange) and normal thymocytes (in grey). STAG2/LMO2 cell lines are colored red. B, The schema of gene-edited cell line models. C, Starburst plot comparing MOLT14-EV with MOLT14-STAG2 for peaks of H3K27ac and their corresponding gene expression. Each circle indicates detected H3K27ac peaks by MACS2 and the circle size represents the p-value of each peak. The bottom-left section includes higher peaks with higher expression in MOLT14-EV. D, H3K27ac (orange), STAG1 (green), and STAG2 (red) binding and RNAseq (blue) coverage at the CD34 locus in MOLT14-EV and MOLT14-STAG2 cells in duplicates. The black squares indicate regained STAG2 binding in MOLT14-STAG2. E, Differentially expressed genes in PF382-STAG2KO (n = 3) compared with PF382-EV (n = 2) in the volcano plot. F, Pathway analysis using up- or down-regulated genes (adjusted P < 0.01 and fold change >2 or < -2) in PF382-STAG2KO compared to PF382-WT. G, Up- and down-regulated genes in PF382-STAG2 KO model (green) and primary STAG2/LMO2 subtype T-ALL cases (red) are shown. H, Average ChIP-seq coverage of STAG1 in PF382-WT and PF382-STAG2 KO lines around common STAG1/STAG2, STAG1, and STAG2 binding regions detected from PF382-WT. I, Starburst plot comparing PF382-STAG2 KO with PF382-WT for peaks of H3K27ac and their corresponding gene expression. The top-right section indicates higher peaks with higher expression in PF382-STAG2 KO.
Figure 5 Drug screening in STAG2/LMO2 T-ALL showed talazoparib, HDAC, and CDK inhibitors as potential target therapy. A, The result of the dose-response analysis for 138 compounds. Each circle indicates tested compounds and the circle size represents the average area under the curve (AUC). EC$_{50}$ was calculated after 72 hours of treatment. EC$_{50}$ <1 μM in both cell lines (bottom left section) were considered “effective”. B, The schema showing the effect of STAG2 inactivation in DNA replication and PARP inhibitor in DNA damage repair (DDR) system. STAG2 inactivation induces stalled replication forks, leading to their collapse and double-strand DNA break (DDB). PARP inhibitor blocks DDR of single-strand DNA break and causes DDB. DDR for DDB is also hindered by PARP inhibitors due to PARP1-DNA trapping. HR, homologous recombination; NHEJ, non-homologous end joining. C, The dose-response curves of STAG2/LMO2 T-ALL lines (MOLT-14 and PER-117) and STAG2 wild-type T-ALL lines (PEER and LOUCY) treated with PARP inhibitor, talazoparib in triplicate. EC$_{50}$ was calculated after 48 hours of treatment. D, The synergistic effect of low-dose HDAC inhibitor, vorinostat (0.1 μM and 0.2 μM), with talazoparib was shown in the dose-response curves and in the highest single agent (HSA) synergy score in PER-117 (n=3). E, LC$_{50}$ value of patient-derived xenografts (PDX) cells from γδ TCR positive STAG2/LMO2 T-ALL tested by a panel of 26 drugs in duplicate. LC$_{50}$ values for each tested drug in reference T-ALL cell lines were shown in black lines. LC$_{50}$ was calculated after 96 hours of treatment. F, The dose-response curves of PDX cells with STAG2/LMO2 subtype treated by talazoparib and prednisolone for 96 hours in duplicate.
