Abstract

**Background:** Unhealthy alcohol use negatively impacts many components of health and wellness, including mental health conditions like major depressive disorder (MDD). Globally, gender differences are common for both alcohol use behaviors and MDD, but these differences have not been studied within Moshi, Tanzania. To provide more effective and culturally appropriate mental health treatments, gender nuances around these conditions must be known.

As such, this study aims to explore gender differences in MDD, alcohol use, and other aspects of mental well-being among patients at Kilimanjaro Christian Medical Center (KCMC) in Moshi.

**Methods:** Six hundred and seventy-six patients presenting for care at the KCMC Emergency Department (ED) and Reproductive Health Centre (RHC) were enrolled in this mixed-methods study between October 2021 and May 2022. Patients were selected through systematic random sampling and completed quantitative surveys including the Alcohol Use Disorder Identification Test (AUDIT) and the Patient Health Questionnaire 9 (PHQ-9). Nineteen patients were purposively chosen from the study population to participate in in-depth interviews (IDIs) exploring topics related to alcohol use, gender, and depression. Descriptive frequencies, univariate log-binomial regressions, and a linear regression model were used to analyze quantitative data, all of which were analyzed in RStudio. A grounded theory approach was used to analyze all IDIs in NVivo.

**Results:** Average [SD] PHQ-9 scores were 7.22 [5.07] for ED women, 4.91 [4.11] for RHC women, and 3.75 [4.38] among ED men. Similarly, ED women held the highest prevalence of MDD (25%) as compared to RHC women (11%) and ED men (7.9%) (p<0.001). Depressive symptoms were associated with higher AUDIT scores only for ED men (R² = 0.11, p<0.001). Our qualitative analysis showed that while present for women, social support networks were notably absent for men in Moshi, the lack of which was seen to play a
role in alcohol use. For men, alcohol was described as a coping mechanism for stress.

**Conclusion:** Intersectionality of gender, alcohol use, and depression is influenced by sociocultural and behavioral norms in Moshi. As such, multi-layered, gender-differentiated programming should be considered for the treatment of substance use and mental health conditions in this region.
Introduction

Alcohol is a significant contributor to the global burden of disease, having been directly linked to the onset of diabetes, certain cancers, sexually transmitted infections, cardiovascular and gastrointestinal diseases, as well as injuries and violence (1–3). Another key but often understudied contributor to the alcohol-related burden of disease is its impact on mental health. Worldwide, over 95 million people have been diagnosed with alcohol use disorder (AUD), a highly disabling condition characterized by harmful drinking and the inability to stop or control one’s drinking habits (4–6). Depression is the most common mental health disorder to co-occur with AUD (7–11), and both depression and AUD commonly co-occur with other mental health conditions, such as other substance abuse disorders, anxiety, dementia, and psychosis-related disorders. One-third of individuals diagnosed with AUD meet the criteria for major depressive disorder (MDD), and studies have shown that those with an AUD diagnosis have a 3.7 times greater risk of acquiring MDD (8,12,13). On its own, depression is the leading cause of disability globally, and when AUD and MDD co-occur, the severity of depression is greater than when it occurs alone (9,12,14–16).

Mental health and AUD are poorly studied in many low- and middle-income countries (LMICs), with few resources and trained personnel available to treat disorders that arise within the general population (17–19). This healthcare gap is especially concerning given that alcohol use and AUD are rising in LMICs (12,20–22). For example, there are only 55 psychologists and psychiatrists in Tanzania, a nation of more than 63 million people (23). Tanzania, which is situated on the Eastern coast of the African continent, has especially high rates of alcohol use and AUD (24). Though the prevalence of AUD is 5.1% globally and 3.7% within the World Health Organization’s (WHO) Africa region, 6.8% of Tanzanians tested positive for AUD, and
20% partook in heavy episodic drinking (24,25). In Moshi, a suburban town in Northern Tanzania, increasing and unhealthy alcohol use is especially concerning given its availability, low cost, local practices that normalize intake from a young age, and common integration of alcohol into sociocultural practices (26–29).

Gender is another important variable that can influence the presentation and rate of onset of both AUD and MDD, as well as alcohol use behaviors. Worldwide, men tend to drink larger quantities of alcohol, but women have higher rates of depression. In 2016, for example, the worldwide average annual alcohol intake was 19.4 liters for men and 7.0 liters for women (24).

Greater alcohol use among men is likewise seen in Tanzania, where men are 5 times more likely to have AUD than women (24).

Conversely, 3.0% of women but 1.8% of men worldwide had MDD, with women also experiencing a greater proportion of depression-related disability (30). When adjusting for age, women had a disability-adjusted life year (DALY) rate of 564 compared to 354 for men, meaning globally, women lost 210 more years of healthy life from depression-related disability or premature death than men (31).

Within Moshi, gender has also been shown to impact alcohol use behaviors, with a greater societal stigma against women’s drinking, leading to decreased intake but also more secretive use behaviors among those who do drink alcohol (32,33). This stigma and the resulting tendency toward private drinking have important consequences, negatively affecting women’s ability to access appropriate alcohol-related treatment and care services. Stress has been identified as a significant contributor to drinking for both genders in Moshi, with relationship stress for women and financial stress for men facilitating increased alcohol consumption (32).
The prevalence of depression has been well-studied among specific patient groups in Moshi, including older adults (34), pregnant women (35), and people living with HIV (36). Data on depression rates among other populations in Moshi, though, is scarce, and the interplay of depression with AUD and the effects of gender in this context are even less well-studied. Since gender may be a key driver of AUD and mental health disorders, a better understanding of the role gender plays in these health conditions could help inform and design more effective treatment options, guide local health policy, and improve long-term patient outcomes in this setting. This paper aims to help advance these long-term goals and build upon previous work in this region that has examined depression rates among specific patient populations (35,37,38), estimated rates of alcohol use and AUD (26,39), and explored gender differences in alcohol use in Moshi (33,40). Our paper aims to (1) quantitatively compare gender differences in rates of MDD, (2) qualitatively explore the relationship between alcohol use and mental well-being, and (3) assess how this relationship varies according to gender among Emergency Department (ED) and Reproductive Health Center (RHC) patients at the Kilimanjaro Christian Medical Center (KCMC).
Methods

Study Design Overview

Between October 2021 and May 2022, mixed-methods data were collected to explore gender differences in alcohol consumption in Moshi, Tanzania, an urban town of over 200,000 residents. Data were collected at the Kilimanjaro Christian Medical Center (KCMC), a large referral hospital in the region that provides care to over 1.9 million people (41). Data consisted of quantitative surveys and qualitative in-depth interviews (IDIs) with patients at KCMC’s Emergency Department (ED) and Reproductive Health Center (RHC). These two sites were chosen to better understand harmful alcohol use behaviors in the ED and to provide a primarily female perspective from the RHC.

During the study period, 676 patients met inclusion criteria and were enrolled through a systematic random sampling strategy to ensure an unbiased representation of each patient population. Of those enrolled, 21 participants had incomplete surveys and were excluded from the quantitative analysis. The remaining 655 survey reports were used to determine the prevalence of MDD by gender and the association between MDD and AUD. Out of these enrolled patients, 19 were selected to participate in IDIs via purposive sampling. This qualitative component allowed for a deeper exploration of how gender impacts the overall relationship between mental health and risky alcohol use behaviors.

Exclusion Criteria

All study participants were recruited from KCMC’s RHC or ED. Participants were excluded from the study if they were under 18 years of age, prisoners, not fluent in Kiswahili, or unable to provide informed consent. In addition, if the patient was not clinically sober, medically
stabilized, or not well enough to complete the survey verbally on their own, they were excluded from the study.

Quantitative Data

Procedures

All subjects were enrolled through a systematic random sampling strategy. Using ED and RHC intake triage registries, every third patient presenting for care was approached for study participation, with the exception of ED women. Every ED women patient was approached as KCMC’s ED sees significantly more male patients than females. Tanzanian, Kiswahili-speaking research assistants provided a study overview to same-gendered patients in quiet, private clinic spaces once a patient had been medically stabilized and was clinically sober. If the patient was interested in participating, a thorough discussion of the study, including potential risks and benefits, ensued. Individuals were free to ask questions or decline participation. If the patient was willing to participate in the study, written consent was obtained, and survey questions were read orally. Responses were recorded by the research assistant to encourage participation from all literacy levels.

Instruments

The Patient Health Questionnaire 9 (PHQ-9) was used to quantitatively assess depressive symptoms and estimate the prevalence of MDD among study participants. This survey tool, which is used globally as a clinical marker for depression, has been translated and clinically validated in Tanzania in the local language of Kiswahili (42–45). The PHQ-9 is composed of 9 questions related to depressive symptoms, such as having poor appetite, poor sleep regulation, or thoughts of self-harm, with responses tallied on a Likert-type scale ranging from 0, “not at all,” to 3, “nearly every day” over the previous two weeks. Scores thus range from 0 to 27, with
higher scores indicating more severe depressive symptoms. Previous studies using the Kiswahili version of the PHQ-9 have determined 9 to be the optimal cut-off point for identifying a major depressive episode, meaning a patient has experienced five or more depressive symptoms for at least a two-week period (42,46). As such, scores of 9 or greater were of primary interest in this analysis to assess the prevalence of likely depression.

The Alcohol Use Disorder Identification Test (AUDIT) measures overall alcohol consumption and assesses for unhealthy alcohol use behaviors. AUDIT scores range from 0 to 40, with higher scores representing increasingly unsafe use. This survey tool was designed to flag patients who display signs of Harmful or Hazardous Drinking (HHD) (47–49). HHD is defined as drinking habits that place a person at risk for experiencing negative health outcomes from their drinking. HHD is measured through AUDIT as scores greater than or equal to 8 (47–50). AUDIT has been translated and cross-culturally validated at KCMC with a similar study population (49).

Analysis

We quantitatively assessed the prevalence of MDD and HHD among ED male, ED female, and RHC female patients. PHQ-9 and AUDIT scores are presented as means with standard deviations, except when dichotomized according to the recommended cut-off points to assess depression and HHD. For PHQ-9, scores of 8 or less were labeled as ‘no MDD,’ and scores of 9 or more were characterized as ‘MDD.’ Similarly, for AUDIT, scores of 7 or less were labeled as ‘no HHD,’ and scores of 8 or more were characterized as ‘HHD.’ When dichotomized, HHD and MDD are presented as descriptive proportions.

The relationship between PHQ-9 and AUDIT scores was also assessed through a linear regression model, with PHQ-9 scores standing as the dependent variable and AUDIT scores as
the independent variable, and through a univariate log-binomial regression. The latter was used
to test unadjusted associations between binary predictors of MDD and the binary outcome
variable (e.g., MDD status), with relative risks (RRs) as the measure of association. Binary
predictors of MDD status that were tested included male gender, different clinical groups, HHD
status, and whether treatment was sought for alcohol use and/or psychiatric reasons. Wald
confidence intervals, using log-based methods, were used to calculate 95% confidence intervals
for reported relative risks.

Quantitative data were measured across all three patient groups instead of by gender
alone to illustrate differences in MDD burden between the two clinical sites. Further, since the
ED and RHC have distinct patients presenting for care, a delineation in scores more accurately
described both populations. All quantitative data were analyzed in RStudio (version 1.4) using
user-tested packages.

Qualitative Data

Sampling

Out of the 676 enrolled participants, 19 were selected via purposive sampling to
participate in IDIs. Reviews of qualitative work have demonstrated that interviewing 20
participants is sufficient for research study saturation when study aims are narrow (51). To
obtain a gender-balanced perspective, the team aimed to interview five female ED patients, five
female RHC patients, and ten male ED patients, or cease once saturation was reached. Saturation
in the study was defined as the lack of new themes or information after three consecutive
interviews and was reached only for ED males after nine participants were interviewed. At this
point, qualitative data collection was terminated, leaving 19 IDIs collected in total.
Purposive sampling was used to ensure a diverse demographic background and alcohol use experiences among selected participants. This included selecting participants from differing ages, religions, income groups, professions, and marital statuses and encompassing patients who held a diverse range of alcohol use behaviors, from complete abstinence to heavy use. Research Assistants also worked to incorporate those with notable personal experiences with alcohol, such as those who used to drink heavily but quit or have had a close friend or relative drink excessively. To maintain unbiased selection, interviewee characteristics were reviewed monthly by the study lead, and recruitment was revised accordingly.

**Procedures**

Selected participants were approached to participate in an IDI after the conclusion of the quantitative survey or through a subsequent phone call. Due to the potentially stigmatizing nature of the study topic, emphasis was placed on maintaining confidentiality for all participants, for example by not mentioning the specific study topic until it was confirmed that the participants were in a private space. IDIs were conducted in a private unoccupied room at KCMC with a gender-matched research assistant who had previously formed a relationship with the patient during the initial survey.

Interviews were conducted in Kiswahili using a semi-structured interview guide. The interview guide included open-ended questions with probes built in for additional questioning when the subject matter was unclear, of interest, or inconsistent. After an early review of quantitative and qualitative data, interesting trends around alcohol use, depression, and mental well-being arose. Thus, the research team amended the interview guide to include the following questions: “Is there a relationship between depression and alcohol use? If yes, please explain”; “Is the burden of alcohol use and depression higher among either men or women? Why or why...
not?" This change was implemented with IRB approval after the 7th IDI was conducted. Aside from these additions, the same interview guide was used for all participants. Participants were provided with refreshments halfway through the interview session and received a small stipend of 5,000 TSH (approximately 2.25 USD) for travel reimbursement.

**Analysis**

Qualitative interviews were analyzed using a grounded theory approach to allow new themes to arise organically and be fully explored (52). Based on the first four interviews, a codebook was developed by the primary data analyst and the Tanzanian research team using both deductive and inductive coding schemes. To ensure cultural pertinence and maintain content validity, the codebook was consistently discussed and modified to include additional themes from new interviews.

The primary data analyst trained the Tanzanian research team on qualitative analysis and coding using NVivo 12 software. All team members coded the first three interviews individually and then discussed them to maintain coding reliability. If disagreements were present in coding schemes, the team discussed them until a consensus on the code was reached. This process continued until an 80% agreement was reached among the research team. After the analysis of the remaining 16 interviews, the analysis team approved the final coding, and content memos were created for each theme.

**Research Ethics**

Ethical approval for this study was obtained from the Duke University Institutional Review Board, the Tanzanian National Institute of Medical Research, and the Kilimanjaro Christian Medical University College Ethical Review Board prior to the onset of any data collection. Data were shared only through a data share agreement and were maintained in a de-
identified manner as much as possible. Personal health information was used for screening and
enrollment but was de-identified when data were stored and analyzed.
Results

Quantitative

This study was composed primarily of female participants, most of whom were Christian (n = 529, 79.5%), were employed (n = 371, 56.6%), and were living with a partner either in a registered or unregistered marriage (n = 414, 62.2%) (Table 1). ED men were found to drink the highest quantities of alcohol, do so the most frequently, and spend the most money on alcohol each week of all three patient groups. The female RHC patient population had the youngest average age, which may be due to the fact that the RHC sees a large number of women who are of childbearing potential.

The highest average [SD] PHQ-9 score belonged to ED women (7.22 [5.07]), followed by RHC women (4.91 [4.11]) and ED Men (3.75 [4.38]) (Table 2). Across all patient populations, ED women also had the highest prevalence of MDD (31%), followed by RHC women (17%) and ED men (16%) (Table 2). Differences in average PHQ-9 scores and prevalence of MDD were statistically significant (P-Value < 0.001) across the three patient groups (Table 2). More patients from the RHC women (10%) population had sought psychiatric treatment than ED women (8.9%) and ED men (7.1%), but this difference was not statistically significant (P-Value = 0.895).

Female patients exhibited a statistically significant (p <0.001) increased risk of MDD status, with a relative risk of 1.15 (95% CI: 1.07 - 1.23) (Table 3). This corresponds to a 15% increased risk of having MDD as compared to their male counterparts. In particular, women attending the ED (e.g., ED women) demonstrated a 71% increased risk of MDD compared to other clinical groups, with a relative risk of 1.71 (95% CI 1.43 - 2.06). In contrast, RHC Women and ED Men exhibited a significantly reduced risk of MDD by 33% (RR: 0.67, 95% CI: 0.49 -
0.92) and 58% (RR: 0.42, 95% CI: 0.22 - 0.79), respectively. Significant increases, or decreases, in the relative risk of MDD were not observed among individuals with HHD status or among those who sought psychiatric treatment (p > 0.1).

Finally, in looking at the relationship between alcohol consumption and depressive symptoms, AUDIT and PHQ-9 scores were found to be linearly associated only among ED men (R² = 0.11; p<0.001) (Figure 1). No significant linear association was found between depression and alcohol use among ED women (R² = 0; p<0.668) nor RHC women (R² = 0.02; p<0.014).

Unadjusted univariate associations between predictors of MDD and MDD, reported as RR (95% CI).
Figure 1: Linear Regression between PHQ-9 and AUDIT Scores across Patient Populations
Nineteen patients (ED women, n = 5; RHC women, n = 5; ED men, n = 9) between the ages of 20 and 70 years participated in an IDI. While the majority were Christian (n = 15, 80%), education levels, relationship status, and alcohol use among IDI participants varied widely. Some participants held only primary-level education, while others held an advanced degree, were single, married, or divorced, and some never consumed alcohol while others had 3 to 4 drinks per sitting almost every day of the week.

Two overarching themes were deductively identified from the 19 completed IDIs: (1) the relationship between alcohol use and mental well-being and (2) gender imbalances in the effect of alcohol use on mental well-being (Table 4). Within the first theme, participants noted that alcohol consumption drove financial stress among men while also being used as a coping mechanism for stress. In the second theme, IDI participants noted a distinction in the strength of men versus women’s social support networks used to deal with stressful situations. The relative lack of support for men impacted their alcohol consumption behaviors and negatively influenced their overall mental health.

Relationship Between Alcohol Use and Mental Well-Being
Alcohol use as a contributor to financial stress

Respondents reported that alcohol consumption exacerbated life stressors, mentioning an increase in monetary stress among both genders, but especially in men. Exemplifying this, one respondent highlighted the financial stress created in his own life by his overconsumption of alcohol and how it affected his mental state and his family’s financial opportunities.

“I was drinking too much. We used to start drinking from 5pm in the evening until 1am at night! And you spend more than 200,000-300,000 shillings per night, and the wife does not know! So, we used to drink strong spirits like Konyagi, 3-4 big bottles per night. Thus, that time of my life was so boring and miserable. That habit put me under stress and depression for about a year. My life got back to zero. I couldn’t afford even paying school fees for my kids.” (30 to 39-year-old man, PHQ-9 = 7)

From this time spent drinking, he concluded that “alcohol never reduced stress.” Rather, because of his drinking, his “stress was even worse”. Another respondent described how men “spend all the money” on consuming alcohol “and come back home with nothing” (50 to 59-year-old man, PHQ-9 = 1), causing financial distress. A female participant shared:

“There was a day I was stressed and I decided to go out for drinking and I ended up spending too much money, more than what I planned to spend. The next morning, I regretted everything a lot and I blamed alcohol.” (20 to 29-year-old woman, PHQ-9 = 15)

Not only did alcohol consumption lead to financial stress, but reciprocally, interviewees alluded to financial stress driving increased alcohol consumption. The anxiety that arose when
men were unable to fulfill their perceived role as financial providers drove men to drink to lower
their distress.

“You may find a man working but not gaining enough to provide well for himself and his
family, so he becomes so stressed as he is not respected as a provider. As a result, he
falls into alcohol drinking in order to get rid of his problems.” (30 to 39-year-old
woman, PHQ-9 = 5)

Alcohol use as a coping mechanism for stress:

The cyclical pattern between alcohol consumption and financial stressors was mimicked
throughout other interviews and illuminated the use of alcohol as a coping mechanism for stress.
Participants widely suggested that alcohol is used to mitigate their own general stress or “life
hardship” (20 to 29-year-old man, PHQ-9 = 0) within their community when proper treatment
was unavailable.

"Many people who drink alcohol excessively use alcohol as a coping mechanism to
handle or reduce stress and life difficulties such as losing a loved one or family
problems.” (30 to 39-year-old woman, PHQ-9 = 13)

Another participant provided a personal experience of harmful alcohol use to cope with loss
within their own family:

“There was a time when my mom started unhealthy drinking after my dad passed away.
She started that as a coping mechanism of losing my dad. It took her six months of
unhealthy drinking. She was complaining about missing him so much and she was
drinking a lot to the point where we had to carry her.” (20 to 29-year-old woman, PHQ-9
= 15)
However, reliance on alcohol to reduce stress only instigated a repetitive chain of deleterious behaviors. Utilizing alcohol to relieve stress was described by one participant as “pouring water in a jar that is leaking” (20 to 29-year-old man, PHQ-9 = 0). In other words, alcohol provided short-term relief, but lacked any long-term benefit to psychological well-being or sustainable solutions to mental distress.

The negative impacts that resulted from the use of alcohol as a coping mechanism were explored by another participant, who shared:

"When people face troubles they drink too much... [They] mistakenly use alcohol as a way to solve their problems. After becoming sober again they realize that the problems are still there. They get even more depressed because they have lost both time and resources on a wrong thing and find themselves drinking even more than before. The cycle goes on and on." (30 to 39-year-old woman, PHQ-9 = 5)

Overall, most participants had well-defined ideas regarding alcohol use as a coping mechanism for stress, life challenges, and depression, as well as the negative, cyclic impacts resulting from excessive use within their community.

**Gender Imbalances in the Effect of Alcohol Use on Mental Well-Being**

The second central theme identified in IDIs was the gendered differences in how alcohol use impacts mental well-being and vice versa, with almost all participants agreeing that the effects were more severe among men.

“Most men are affected more than women, because in my community men have a lot of responsibilities as compared to women. So, by the time he can’t meet his goals, he ends up being frustrated and resorts to abusing alcohol and depression occurs.” (20 to 29-year-old man, PHQ-9 = 0)
While not necessarily normative, the lack of healthy outlets for men, strong social networks for women, and the unhealthy expectations of traditional male and female roles were all factors found to influence the relationship between alcohol consumption and mental well-being that disproportionately burdened men. Thus, highlighting the gender inequity in Tanzanian culture that is influencing alcohol consumption and mental well-being.

**Lack of healthy outlets for men encourages alcohol intake**

Throughout the interviews, many respondents highlighted a lack of healthy emotional outlets for men to deal with stressors or discuss their challenges – as said by one, “*a man never cries*” (20 to 29-year-old woman, PHQ-9 = 4), meaning that it was looked down upon socially for a man to express his emotions. This drove men to cope with stressful life situations and depression through alcohol:

> “*Men only show a happy face even when they are stressed, because it is not easy for a man to talk about his problems. Many men drink alcohol to relieve their pain. I think a lot of men feel that showing their feelings of pain is a weakness, and that he will look like a weak man.*” (30 to 39-year-old woman, PHQ-9 = 13)

> “*This problem affects more men than women in my society...They are always taught to keep the problems to themselves as a sign of strength or manhood. That’s why, when problems overwhelm them, they get into depression. They can’t tell anyone so they get into drinks and drink alone.*” (20 to 29-year-old woman, PHQ-9 = 4)

The phrase “a man never cries” and the social significance of being labeled a weak man, according to another respondent, created more mental distress and depression among men compared to women. This burden was noted to be lesser on women because they were socially...
allowed to express feelings of weakness and hardship. One participant labeled these cultural views of masculinity as “toxic”, and called for broader societal changes, such as creating new norms for men to be more open and honest about their challenges.

“You know, naturally men are meant to be strong. Sometimes men experience problems but you will never see them sharing to a fellow man, you know why? That’s a sign of weakness. And this is the toxic feelings that we as men create every day, contrary to women who like to share anything they are going through. Through sharing you are releasing all the pains and sorrow and bad feelings... so the heart feels fresh and strong! I think this is the main reason why men get depressed compared to women.” (50 to 59-year-old man, PHQ-9 = 1)

It was not a lack of desire, but rather a sociocultural norm that meant men were unable to share emotionally with other men. One respondent expressed his desire to talk about personal troubles, but found he is only able to do so when he and his friends are intoxicated and there is little chance of the event being remembered:

“When I am stressed and I go out with my friends and we are drunk, I will open up all my problems because I am sure the next day they will not remember what I shared with them. I see it’s a good way to let everything out as I am sure the next day everything will be forgotten.” (20 to 29-year-old man, PHQ-9 = 15)

The desire to share his hardships only when his social network will forget further illuminates the overall lack of socially acceptable healthy outlets for men to discuss their mental well-being.

Women’s social networks:

In stark contrast to men’s inability to share with other men, robust social networks among many women in Moshi were seen as a protective factor in combating stress – “I think men are more
stressed and they hide their stress on alcohol use. Women, when they are stressed, talk a lot and that helps them to reduce stress” (20 to 21-year-old woman, PHQ-9 = 15). It was seen as easy and commonplace for women to talk with one another, and alcohol was not needed to facilitate these kinds of conversations – “A woman may drink one beer and start to open up all her problems, while it takes a man to drink even ten beers and he still may not open up about his problems” (20 to 29-year-old woman, PHQ-9 = 15). These social networks among women were so strong that women who were strangers still came to each other for help. “When women have a problem, they talk about it. That helps to take their pain away. A woman can meet anyone, even if she doesn't know her, and talk to her to relieve her heartache. This helps many women to cope with stress.” (30 to 39-year-old woman, PHQ-9 = 13)

In summary, participants proposed that depression and harmful alcohol consumption are strongly influenced by cultural norms. One primary effect of local norms is reduced autonomy and financial disenfranchisement among women, which in turn influence their rates of depression and alcohol use. Another primary effect is the increased pressure placed on men to be the financial caretakers for their families. Social norms mediate that in the face of this stress, men are expected to “keep problems to themselves as a sign of strength” and “find solutions all by yourself,” while women in the community are encouraged to talk to other women and find it easy to find “a listening ear” (20 to 29-year-old woman, PHQ-9 = 4). In effect, women are shown to employ healthier coping strategies while men utilize unhealthy coping strategies in the form of alcohol use.
Discussion

This study, which is among the first of its kind in Northern Tanzania, investigated the intersection between gender, alcohol use, and depression among ED and RHC patients at KCMC. Existing literature within Moshi has identified high levels of alcohol use, described depression among specific patient populations, and explored gender differences in alcohol consumption and alcohol-related consequences (26,27,32–36,38,53). Our mixed-methods analysis builds upon this literature to help inform the design and implementation of more effective mental health-related treatment options in this region.

In our analysis, we found that ED women patients had the highest rates of MDD among the three populations studied, indicating that this group may be particularly in need of more concerted clinical mental health care efforts. Importantly, though, an increasing severity of depressive symptoms in women did not correlate with increased alcohol use. This observation stands in direct contrast to what was observed among ED men, namely a positive correlation between AUD and depressive symptoms. This relationship is supported by our qualitative data, which demonstrate that men in Moshi, but not women, lacked social outlets for dealing with stress, making them more likely to turn to alcohol as a coping mechanism. It appears that social norms disenfranchise women by limiting their autonomy and financial opportunities, which may contribute to higher rates of depression among women. Men, by contrast, face cultural norms of being the main financial provider, which contributes to increased stress. However, in the face of these differing stressors, women employ healthier social coping strategies while men are more likely to remain silent and use alcohol to cope. These findings illustrate the need to take both a cultural and gender lens to mental health treatment in Moshi, utilizing social networks and differentiating interventions by gender to optimize treatment and health outcomes. Interventions
might also seek to examine whether social norms and gendered coping strategies reflect underlying values and goals, or should be reconsidered to better align with these values. For example, previous work based in Kenya has shown the downstream benefits for family and community members when interventions that address both alcohol use and depression are implemented (54–56).

Our results indicate that ED women have the highest rates of MDD among all populations, highlighting the need for mental health interventions to better support this high-risk group. This reflects global differences in the prevalence of depression among men and women, with depression being 50% more common in women compared to men (57). Paralleling our estimates, in a systematic review of 134 studies, Corcoran et al. found the prevalence of depression among women in LMICs was almost twice as high among women living in higher-income countries (58). Within our qualitative data, many interviewees described depressive symptoms without ever stating or naming depression specifically. The hesitancy to label themselves or others as depressed could highlight the mental health stigma that is present in Tanzania and globally (59,60).

Although our results demonstrate higher rates of depression among women, depression was not associated with increased alcohol use among women. Interestingly, though, this was not true for male participants, where depressive symptoms were positively and linearly associated with alcohol consumption. This dichotomy suggests that men's and women’s approaches to alcohol use and stress relief differ significantly. Stress has been widely associated with alcohol use, with previous research conducted by our team identifying stress as a major motivator for unhealthy drinking habits in Moshi (32). A major underlying factor in the gendered differences between stress and alcohol use is the influence of social networks. Our qualitative findings
suggest a higher prevalence of strong social support networks for women, which may be associated with low rates of alcohol use and harmful drinking behaviors. This link is also seen in global data, where social support networks have been seen to offer a protective effect on depression risk (61).

As was noted within our IDIs, the relative absence of emotional support for men may lead them to use alcohol as a coping mechanism for difficult events and thus calls for an increase in healthy emotional outlets for men. While social support networks may be helpful for women experiencing emotional distress, it is still important to acknowledge the larger clinical burden of depression experienced by women in future mental health interventions within this setting.

Particularly, previous research has examined the disproportionate stigma experienced by women who consume alcohol in Tanzania (62). A study recently conducted in South Africa suggests that increasing social support may not be enough to prevent depression among women who are experiencing high rates of stigma (63); therefore, it may be necessary to incorporate additional targeting counseling and advocacy focused on addressing harmful cultural norms and gender inequities that contribute to the greater risk of depression among Tanzanian women. Future mental health-related interventions in this region must be cognizant of cultural norms and resulting behavioral differences underlying mental health disorders to more efficiently and effectively distribute available resources.

The findings discussed thus far highlight the need for gender and sociocultural factors to be more closely considered in mental health-related programs and, more specifically, for there to be greater differentiation in interventions intended for men versus women. For women, the high prevalence of MDD identified in this paper, especially among those receiving care at the ED, points to a need for more robust mental health-related screening, referral, and care services for
female patients. Previous work by our team has highlighted the relevance of expanding these services within KCMC’s ED (64), but in the context of this paper, it is especially important to note the potential benefit that this could have among women, given their significant mental health burden.

In contrast, for men, the linear relationship between alcohol use and depressive symptoms in this analysis indicates that local alcohol-related interventions may benefit from teaching and providing healthy, values-based coping mechanisms when faced with life stressors. Mental health-related treatments that are differentiated by gender have been shown to have greater effectiveness (65–67) and individualized treatments for men may have wider cultural acceptance.

Previous research and clinical trials have also shown the value of incorporating a multi-level approach to mental health and substance use treatment, addressing individual-, family-, and community-level interventions. Mathias et al. found that incorporating multi-pronged elements to care delivery, including increased access to services, greater education around mental health topics, and robust social support networks, was effective in treating patients with severe mental health problems in India (68). In Tanzania specifically, multi-level approaches to mental health care are gaining support (69) and have been locally implemented in the treatment of other medical issues like HIV (70). As such, we recommend that local health policy efforts incorporate these considerations in mental health delivery efforts to provide more effective care for the Moshi community.

Strengths and Limitations

Though this paper offers novel insights into the mental health landscape of Moshi, the data presented here must be considered along with some broader limitations. In terms of qualitative data, specific interview questions on depression and alcohol use were only added
midway through data collection, once the research team recognized the importance of this topic in preliminary analyses. While added later on, saturation on the topic of depression and alcohol use was still reached, and was done so using robust qualitative data collection procedures, including gender matching of interviewers and interviewees, rigorous qualitative training among the research team, and ensured privacy and confidentiality. Therefore, we hold that the IDI data presented here is representative and accurate for the study population.

In addition, some key drivers of MDD such as past trauma, medical conditions, and genetic factors were not measured in the quantitative survey. Information like this could help identify factors within the broader population that should be addressed in community outreach programs. Therefore, we encourage future research to explore the reasons underlying depressive symptoms in this region, especially in the ED women population that was identified as high-risk.

Even in light of these limitations, this study adds meaningfully to the existing literature, standing as the first study to specifically explore the intersection of alcohol use, depression, and gender within Moshi and can serve as a foundation for future related research.

Conclusion

Women in Tanzania are more likely to experience major depressive disorder. Depression was not associated with higher alcohol use among women but was significantly associated with increased alcohol use among men. Women experiencing depression were more likely to rely on healthy coping through emotional support networks, whereas these networks were weaker for men, which may contribute to men using unhealthy strategies such as drinking alcohol when experiencing emotional distress. Our findings highlight the need for future mental health-related interventions in this region to address harmful gender norms, to take gender into greater account.
in the design of interventions, and to include multiple aspects of care delivery designed to address individual, family, and community aspects of overall patient well-being.
