ABSTRACT

BACKGROUND: We investigated effects of APOE ε4 and its interactions with sociodemographic characteristics on cognitive measures in 2,563 South Asians from the Diagnostic Assessment of Dementia for the Longitudinal Aging Study of India (LASI-DAD).

METHODS: Linear regression models were used to assess the association between APOE ε4 and global- and domain-specific cognitive function. Effect modification by age, sex, and education were explored using cross-product interaction terms and subgroup analyses.

RESULTS: APOE ε4 was inversely associated with most cognitive measures. This association was stronger in the older age group (age >68) for general cognitive function, orientation, and language/fluency, as well as in females for memory and language/fluency. Interaction between APOE ε4 and education was mostly nonsignificant.

DISCUSSION: APOE ε4 is associated with lower cognitive function in South Asians from India, with a more pronounced impact observed in females and older individuals.
1 INTRODUCTION

Dementia, a group of neurological disorders characterized by impaired cognitive function, is a leading cause of death, disability, and dependency among older adults worldwide [1,2]. Dementia and cognitive function have significant genetic components, with the \( \varepsilon4 \) allele of the apolipoprotein E (APOE) gene being the strongest genetic risk factor for late-onset Alzheimer’s disease (AD) in many populations [3–5]. For instance, compared to the most common and risk-neutral \( \varepsilon3/\varepsilon3 \) genotype in European ancestry populations, having one \( \varepsilon4 \) allele is associated with an increase of 2-3 times in the risk of AD, while having two \( \varepsilon4 \) alleles is associated with an increase in risk of up to 15 times [6]. Conversely, the \( \varepsilon2 \) allele has been generally associated with reduced AD risk. These APOE alleles have also been linked, to a lesser extent, with global cognition and performance in specific cognitive domains including episodic memory, executive function, and verbal fluency in individuals without dementia [7].

Sociodemographic factors such as age, sex, and education are also associated with cognitive function in older adults[8] and contribute to the risk of dementia [9,10]. A growing body of literature has explored the potential interaction between APOE \( \varepsilon4 \) and these sociodemographic characteristics, yet the evidence remains inconclusive. Specifically, some studies report that the effect of APOE \( \varepsilon4 \) on AD may be more pronounced in young-old adults (e.g., 60-70 years) than in those who are older (>70 years) [6,11,12], females than males [6,13–15], and in those with lower education [16,17]. Similar findings are observed for the interactions of APOE \( \varepsilon4 \) with sex and education with cognitive function as the outcome [18–21]. However, in contrast to AD, the effect of APOE \( \varepsilon4 \) on cognitive function appears to increase progressively with age [22,23]. Other studies, however, have failed to detect any interactions between APOE
and age, sex, or education in relation to cognitive function and dementia [24–27]. Therefore, it is still unclear to what extent these sociodemographic factors modulate \( APOE \, \varepsilon 4 \) associations.

To date, the vast majority of genomic studies on cognitive function and dementia have been conducted in European ancestry populations [28–32]. India is the most populous country in the world with over 4.1 million people estimated to have dementia [2], yet Indian and South Asian populations in general are rarely represented in genomic studies. This lack of representation is concerning as differences in allele frequencies and linkage disequilibrium (LD) patterns across ancestry groups could result in varying genetic effects and associations with disease [33]. Indeed, there is some evidence that the effect of \( APOE \, \varepsilon 4 \) on cognitive function and dementia differs across ancestries and race/ethnicities [34]. An early meta-analysis of clinical and autopsy-based studies, for example, found that the association between \( APOE \, \varepsilon 4 \) and AD was weaker among African Americans and Hispanics compared to Caucasians, but stronger in Japanese [6]. In India, the few studies that have investigated the relationship between \( APOE \, \varepsilon 4 \) and AD suggest that its effect size is similar to that observed in populations of European ancestry [35–38]. However, prior studies in India have primarily relied on geographically restricted samples. Furthermore, India possesses unique cultural, social, and environmental characteristics, such as dietary practices and pathogen or toxicant exposures, that further distinguish it from populations of European ancestry. These closely intertwined factors may be associated with cognitive function and dementia and/or may modulate the genetic effect of \( APOE \, \varepsilon 4 \) in various ways. Therefore, large-scale epidemiological studies employing nationally representative data are needed to comprehensively explore the effects of \( APOE \, \varepsilon 4 \) on cognition and dementia and identify potential effect modifiers in Indian/South Asian populations.
The Diagnostic Assessment of Dementia for Longitudinal Aging Study in India (LASI-DAD) is a population-based prospective cohort study that has collected nationally representative data on Indians aged 60 and older to better understand the determinants of late-life cognition, cognitive aging, and dementia. In this study, we examined the effect of the \textit{APOE} \textit{\epsilon}4 allele and its potential modification by sociodemographic factors including age, sex, and education on cognitive measures in LASI-DAD.

2 METHODS

2.1 Study population

The Longitudinal Aging Study of India (LASI) is a nationally representative sample of more than 73,000 adults from India aged 45 years or older [39]. LASI-DAD is an add-on study of late-life cognition and dementia, in which a subsample of community-residing LASI respondents aged 60 or older were administered in-depth cognitive tests and informant interviews, adopting the Harmonized Cognitive Assessment Protocol (HCAP) developed by the Health and Retirement Study (HRS) to be suitable for the local context and population characteristics [40]. A two-stage stratified random sampling method was used in LASI-DAD to ensure a sample with a broad distribution of cognitive ability including respondents with dementia and mild cognitive impairment (MCI). The respondents were stratified according to their state of residence and their risk of cognitive impairment based on their performance on the cognitive tests and proxy interview (i.e., interview with a family member when the respondent is incapable of participating in the interview) in the main LASI study. Next, within each state, a predetermined sample size proportional to the state's population size was used to randomly select an equal number of respondents at high and low risk of cognitive impairment [40]. The baseline
(Wave 1) LASI-DAD sample consists of 4,096 older adults aged 60 or older, representing >600 ethnically and geographically diverse areas within 18 states and union territories.

2.2 Measures

2.2.1 Whole Genome Sequencing

Whole genome sequencing (WGS) was performed on a total of 2,762 LASI-DAD participants who consented to blood sample collection at MedGenome, Inc (Bangalore, India) at an average read depth of 30. Genotype calling and quality control (QC) on the raw LASI-DAD WGS data were performed at the Genome Center for Alzheimer’s Disease (GCAD) at the University of Pennsylvania [41,42]. Briefly, sample-level quality control included checks for low coverage, sample contamination, sex discrepancies, concordance with previous genotype data, and duplicates [41]. After excluding control samples and samples with low quality and/or unresolved identity, a total of 2,680 samples were retained in the analysis. At the genotype level, each genotype was evaluated and set to missing if read depth was less than 10 (DP<10) or genotype quality score was less than 20 (GQ<20). At the variant level, a variant was excluded if it was monomorphic, was above the 99.8% Variant Quality Score Recalibration (VQSR) Tranche (the quality score was beyond the range that contains 99.8% of true variants), had a call rate ≤ 80%, or had an average mean depth > 500 reads. We further removed variants that were in low complexity regions identified with mdust [43]. After quality control and filtering, we retained a total of 71,109,961 autosomal bi-allelic variants that include 66,204,161 single nucleotide polymorphisms (SNPs) and 4,905,800 indels. Genetic principal components (PCs) were calculated using PCAir [44] to take into account the relatedness in the samples. Specifically, the PCs were first calculated in a set of unrelated individuals (kinship cutoff=0.044) and then
projected to all other individuals. For this analysis, we included 2,607 individuals that are not related at 3rd degree or above. The top 10 PCs were included in all analyses to adjust for population stratification.

2.2.2 *APOE* Genotyping

*APOE* ε2, ε3, and ε4 alleles are defined by two SNPs (rs429358 and rs7412) that lead to changes in the amino acid sequence at positions 112 and 158. Direct genotyping for these *APOE* SNPs was performed on 2,754 LASI-DAD participants using TaqMan assays (Applied Biosystems, Foster City, CA). The resulting genotypes of these two SNPs were then combined to form six possible *APOE* genotypes: ε2/ε2, ε2/ε3, ε2/ε4, ε3/ε3, ε3/ε4, and ε4/ε4. In our primary analyses, we dichotomized *APOE* genotypes based on the presence or absence of the ε4 alleles and classified participants as *APOE* ε4 carriers (i.e., ε3/ε4, and ε4/ε4) or noncarriers (i.e., ε2/ε2, ε2/ε3, and ε3/ε3). We focused on the 2,590 unrelated participants who had both WGS and *APOE* genotyping data. Due to the potential opposing effects of the ε4 and ε2 alleles on cognitive measures, individuals with the *APOE* ε2/ε4 genotype were further excluded from the analyses (N= 27, 1.0%). This left 2,563 participants for inclusion in the primary analyses. A study flow chart is presented in Supplementary Figure 1.

2.2.3 Cognitive measures

We examined a total of seven cognitive measures, including the Hindi Mental State Examination (HMSE) score, five broad cognitive domain scores (orientation, memory, executive functioning, language/fluency, and visuospatial), and a general cognitive function summary score constructed from the five domains. The HMSE score is the Hindi version of the Mini-Mental State Examination (MMSE), a widely used cognitive screening instrument [45]. The
HMSE score ranges from 0 to 30, with higher scores indicating better cognitive functioning.

General cognitive function and domain-specific cognitive performance were derived using factor analysis of the LASI-DAD cognitive battery, as described by Gross et al.[46] These scores were internally standardized to a N(0,1) distribution in the entire sample of 4,096 LASI-DAD participants.

### 2.2.4 Covariates and effect modifiers

We examined several sociodemographic and socioeconomic characteristics that were self-reported by the participants at baseline as covariates. Sociodemographic factors included age, sex, educational level according to a three-tier simplified version of the 1997 International Standard Classification of Education (ISCED-97) codes (less than secondary education, upper secondary education and vocational training, or tertiary education), urban/rural residence, literacy (can read or write), and state of residence. We also included caste and per capita household consumption (in rupees) as measures of socioeconomic status. Respondents self-reported their caste and were classified into four official categories recognized by the Indian government: scheduled caste, scheduled tribe, other backward class (OBC), or no caste/other caste. Per capita household consumption was used to capture the economic status of the respondents and was calculated by taking total household consumption over the previous year for food, household utilities, fees, durable goods, education, healthcare, discretionary spending, transit, and remittances divided by the number of people in the household.

Age, sex, and education were also assessed as potential effect modifiers of the association between $APOE\,\varepsilon4$ and cognitive function. We examined the interaction between $\varepsilon4$ and education using the three-level categorical education variable described above. Nearly half of our
sample (~48.7%) had never attended school, which aligns with the 56.5% illiteracy rate among older adults in India [47]. Thus, we further investigated the interaction between APOE ε4 and a dichotomous education variable, distinguishing between individuals with no formal education and those with any formal education (0 years of education vs. >0 years of education groups). Furthermore, to facilitate interaction and subgroup analyses, age was dichotomized at the sample median (≤ 68 years vs. >68 years) when analyzed as an effect modifier.

2.3 Statistical analysis

The distribution of APOE genotypes and allele frequencies were calculated for the full study sample, and Hardy-Weinberg equilibrium was assessed. APOE genotype and allele frequencies were additionally estimated by 5-year age group ranging from 60 years (smallest age of the sample) to ≥ 85 years. We compared and tested whether the APOE ε4 allele frequency differed by age to assess a potential selective survival bias. Descriptive statistics of the analytic sample were compared by APOE ε4 carrier status using t-test, Wilcoxon rank-sum test, and Pearson chi-square test as appropriate.

We first examined the association between APOE ε4 (carrier vs. non-carrier) and cognitive measures in the full analytic sample using linear regression models. We then tested the interaction between APOE ε4 and age, sex, or education by including the two independent variables and their cross-product term into the same model. We further conducted age-, sex-, and education-stratified analyses to estimate the ε4 effects separately within each subgroup, regardless of whether an interaction was detected. We employed two sets of models for all analyses. Model 1 adjusted for age (if applicable), sex (if applicable), state of residence, and the top 10 genetic PCs. Model 2 additionally adjusted for social- and economic-related variables.
including educational level (if applicable), literacy, urban/rural residence, caste, and per capita household consumption.

As a sensitivity analysis, we repeated all analyses to examine the effects of specific APOE genotypes and their modification by age, sex, and education on cognitive measures. In this analysis, we excluded individuals with the ε2/ε4 (protective/risk allele) and ε2/ε2 (low frequency; N=5) genotypes, and focused on the remaining four possible APOE genotypes: ε3/ε3 (reference group), ε2/ε3, ε3/ε4, and ε4/ε4. We did not test the interaction between APOE genotypes and the three-tier education variable due to the smaller subgroup sample sizes.

3 RESULTS

3.1 Sample characteristics

Supplementary Table 1 provides the distribution of APOE genotypes and alleles in the full study population, as well as by 5-year age intervals ranging from 60 years to ≥ 85 years. The allele frequencies of APOE ε2, ε3, and ε4 were 0.048, 0.844, and 0.108, respectively. There was no significant difference in the frequency of the ε4 allele by age when compared across 5-year age groups (p = 0.813) (Supplementary Table 1 and Supplementary Figure 2). About 19% (n = 497) of the participants were classified as APOE ε4 carriers (18% ε3/ε4 heterozygotes and 1% ε4/ε4 homozygotes). Genotype frequencies observed in the full study sample were in Hardy-Weinberg equilibrium (p = 0.667).

Descriptive statistics for sociodemographic characteristics and cognitive measures by APOE ε4 carrier status are shown in Table 1. The mean age of the participants was 69.56 years (SD 7.29) and approximately 53% (n = 1,358) were female. Seventy-five percent (n=1,926) had
less than lower secondary education, with 48.7% (n= 1,249) participants having no formal education. Twenty-one percent (n= 542) had upper secondary or vocational training, and 4% (n=95) had tertiary education. \textit{APOE} \( \varepsilon4 \) carriers and noncarriers did not differ with respect to age, sex, and state of residence. However, compared to \textit{APOE} \( \varepsilon4 \) noncarriers, \( \varepsilon4 \) carriers were more likely to have less than upper secondary education, reside in rural areas, and score lower on all cognitive measures except visuospatial functioning. Significant differences in caste and per capita household consumption were also found between \textit{APOE} \( \varepsilon4 \) carriers and noncarriers.

\textbf{Supplementary Table 2} provides the correlation among the seven cognitive measures examined in this study. The correlation among the five cognitive domain scores ranged from 0.491 to 0.733. The correlations between the five domain scores and general cognitive function and HMSE ranged from 0.733 to 0.948 and from 0.560 to 0.856, respectively.

\subsection*{3.2 \textit{APOE} \( \varepsilon4 \) and sociodemographic characteristic associations with cognitive measures}

\textbf{Table 2} presents the associations between \textit{APOE} \( \varepsilon4 \) and cognitive measures in the full sample. All effect estimations were in the expected direction, with \( \varepsilon4 \) carriers having lower cognitive function. In models adjusting for age, sex, state of residence, and the top 10 genetic PCs (Model 1), \( \varepsilon4 \) carrier status was associated with all cognitive measures except visuospatial functioning (p < 0.05). Specifically, being an \( \varepsilon4 \) carrier was associated with a 0.095 – 0.142 SD decrease in cognitive scores and a 0.978 points reduction in HMSE score. The associations were slightly attenuated after further controlling for education, literacy, urban/rural residence, caste, and per capita household consumption in Model 2. Nevertheless, the association between \textit{APOE} \( \varepsilon4 \) and HMSE score, general cognitive function, orientation, and memory remained significant (p < 0.05).
Effect estimates and p-values for all other covariates in Models 1 and 2 can be found in Supplementary Tables 3 and 4, respectively. In Model 1, older age was inversely associated with all cognitive measures, while male sex was positively associated with all cognitive measures. These associations stayed largely consistent in Model 2. Education was also independently associated with all cognitive measures. Compared to individuals with less than lower secondary education, those with upper secondary or vocational training education showed a 0.179-0.458 SD increase in cognitive scores and a 1.480 point increase in HMSE score, while those with tertiary education showed a 0.327-0.893 SD increase in cognitive scores and a 2.392 points increase in HMSE score.

Collectively, APOE ε4 carrier status and other covariates in Model 1 explained approximately 18.6% (visuospatial function) to 33.9% (general cognitive function) of the total variance in cognitive measures. Specifically, ε4 carrier status alone contributed between 0.09% (visuospatial function) and 0.51% (HMSE score) of the explained variance. The total variance explained increased to 37.9-62.4% when education, literacy, urban/rural residence, caste, and per capita household consumption were added to the model (Model 2). In this further adjusted model, the individual contribution of ε4 carrier status to the total variance explained ranged from 0.01% to 0.27%.

3.3 Effect modification of age, sex, and education on the associations between APOE ε4 and cognitive measures

We next examined whether the associations of APOE ε4 with cognitive measures were modified by age, sex, and education. Table 3 provides the results from testing the APOE ε4 × age > 68 years interaction term. We found a significant APOE ε4 by age interaction on general
cognitive function, orientation, and language/fluency in Model 2, with the associations being more pronounced in the > 68 years age group (Figure 1). Results from age-stratified analysis suggest that the detected interactions were mainly driven by the significant $\varepsilon 4$ effects on cognitive function, orientation, and language/fluency in the > 68 years age group that were not observed in the $\leq$ 68 years age group (Table 4). We also observed similar results for several of the other cognitive measures, where the $\varepsilon 4$ effect was significant solely in the older age group.

Table 5 presents the results from testing the $APOE \varepsilon 4$ by sex interaction term. In Model 1, an $APOE \varepsilon 4 \times$ male interaction was observed for language/fluency and memory, with the effect of $\varepsilon 4$ stronger in females. While the interaction terms were not statistically significant for the other cognitive measures, sex-stratified analysis showed that $APOE \varepsilon 4$ was associated with all cognitive measures among females except visuospatial functioning, whereas there was no association between $\varepsilon 4$ and any cognitive measures among males (Table 6). Sex differences in the $\varepsilon 4$ effect attenuated in Model 2, but the $APOE \varepsilon 4 \times$ male sex interaction term remained statistically significant for both language/fluency and memory (Figure 2, Tables 5 and 6).

Supplementary Table 5 provides the results from testing the $APOE \varepsilon 4$ by education interaction terms. Using the three-level education variable, all interaction terms between $APOE \varepsilon 4$ and education were not statistically significant except the interaction between $\varepsilon 4$ and upper secondary or vocational training on visuospatial function. A closer examination of the education-stratified analysis showed that most significant $\varepsilon 4$ associations were predominantly observed in the less than lower secondary education group (Supplementary Table 6). Given that this group constituted ~75% of our sample, with more than 64% of them having no formal education, we further explored the $APOE \varepsilon 4$ by education interaction by separating our sample into two categories: those with no formal education (0 years of education) and those with any type of
formal education (>0 years of education). We found no interaction between APOE ε4 and the dichotomous education variable on any of the cognitive measures (Supplementary Table 7). However, when we examined the ε4 associations with cognitive measures separately within these two subgroups, we observed that ε4 was associated with all cognitive measures except visuospatial function among individuals without formal education in Model 1 (Supplementary Table 8). In contrast, among those who had received some education, ε4 was only associated with HMSE score and orientation domain score. This pattern of association largely persisted in Model 2, except for the loss of significance in the associations between ε4 and executive function and language/fluency among those with no formal education.

3.4 Sensitivity analysis

Sensitivity analyses examining APOE genotypes showed that the main effect of ε3/ε4 compared to ε3/ε3, as well as its potential modification by age, sex, and education closely mirrored what we observed for ε4 carriers in the primary analyses (Supplementary Tables 9-15). Furthermore, even though not statistically significant, we found that the effect of ε4/ε4 on cognitive function was in the expected direction, with lower scores observed among ε4/ε4 compared to ε3/ε3 in the full sample and within age, sex, and education subgroups. Contrary to our expectation based on previous literature, we did not consistently observe a clear dose-response relationship between the number of ε4 alleles and worse cognitive function, as indicated by the smaller magnitude of effect in ε4/ε4 homozygotes compared to ε3/ε4 heterozygotes in the full sample, as well as within subgroups of age ≤68, male sex, and 0 years of education (Supplementary Tables 9, 11, 13, and 15). However, we caution that our sample included only a small number of individuals carrying the ε4/ε4 genotype (n=36), which likely contributed to our inability to establish statistically significant associations or interactions.
Finally, results from the sensitivity analyses also revealed an association between $APOE\,\epsilon2/\epsilon3$ genotype and lower visuospatial function when compared to $\epsilon3/\epsilon3$ (Supplementary Table 9). We did not detect any significant interactions between the $\epsilon2/\epsilon3$ genotype and age, sex, or education (Supplementary Table 10, 12, and 14). Nevertheless, an adverse effect of the $\epsilon2/\epsilon3$ genotype on visuospatial function was found among females and individuals aged 68 years and older, but not among males and those younger than 68 years (Supplementary Tables 11 and 13).

4 DISCUSSION

In this large, nationally representative sample of Indians aged 60 and older, $APOE\,\epsilon4$ carrier status was associated with lower cognitive function, both globally and in multiple specific domains. We also found that females may be more susceptible to $\epsilon4$ effects on memory and language/fluency, while those aged 68 years and older may be more susceptible to $\epsilon4$ effects on general cognitive function, orientation, and language/fluency. The $\epsilon4$ frequency was 10.8% in our sample, which is consistent with the 10.0% $\epsilon4$ frequency reported in the Genome Aggregation Database (gnomAD) for South Asians [48] and reaffirms the relatively lower $\epsilon4$ prevalence among South Asians compared to the global frequency of 14% [3]. However, this allele is important as it remains the strongest known genetic risk factor for AD and cognitive function/decline worldwide. Studying its effect on cognitive function contributes to our overall understanding of the genetic architecture of cognitive aging in the Indian population.

We found modest adverse effects of $APOE\,\epsilon4$ on a broad range of cognitive domains. Direct comparison of $\epsilon4$ effects on cognition is challenging as methodological factors, including sample size, study population (e.g., participant age range), and study design (e.g., measurement and modeling of cognitive measures), may vary substantially across studies. Nonetheless, the
observed domain specificity of ε4 effects on cognition in our study is in line with two previous meta-analyses in cognitively healthy individuals of European ancestry which indicate that ε4 carriers perform worse on measures of global cognition and episodic memory, but not on language/fluency (verbal ability) and visuospatial function [22,49]. However, contrary to these meta-analyses, we did not find an association between ε4 carrier status and executive function after adjusting for sociodemographic and socioeconomic factors. These results also differ slightly from earlier LASI-DAD studies [50,51], which examined genotype chip data on 932 participants and found no significant ε4 effects on cognition, potentially due to inadequate power and a more restricted geographic sample than the current study.

We also found a relatively consistent, though not always statistically significant, pattern across cognitive measures whereby the magnitudes of the ε4 effects on cognition appeared stronger among those at least 68 years than younger individuals. This is consistent with several studies indicating that the negative effect of APOE ε4 on cognitive function increases with advancing age [22,52,53]. The molecular mechanisms underlying the potential age-dependent ε4 effects on cognitive function remain unknown. One possibility is the resource modulation hypothesis [53], which posits that effects of common genetic variants, such as APOE, may become stronger in older age when neurochemical and anatomical brain resources are declining [54,55]. However, the observed interaction between ε4 and age could also be explained by the increasing presence of preclinical, mildly cognitively impaired, or diagnosed dementia cases with advancing age, as ε4 may be more robustly associated with these cases, creating a seemingly stronger association between ε4 and cognition in older individuals. Not all studies have observed this interaction [49,56]. In fact, one study showed that ε4 effects on global cognitive functioning and episodic memory were inversely related to age, although these
correlations were not statistically significant [49]. These inconsistent findings may be partly due to methodologic differences, such as sample size, age range of the participants, and measurements of cognitive function across studies.

We found that the association between APOE ε4 and cognition was stronger in females than males for language/fluency and memory, which is consistent with a growing body of literature. For instance, early studies found that the ε4 allele confers a greater risk for AD in women than men [57,58]. These findings were replicated in a seminal meta-analysis that reported that female ε4 carriers had a higher risk of developing AD compared to both female ε4 noncarriers and male ε4 carriers [6]. More recently, studies have shown that ε4 effects on AD biomarkers, including cerebrospinal fluid biomarkers (Amyloid-β and tau), brain metabolism, and brain structure [15,59–61], as well as on cognitive function and decline [18,62,63], are also stronger in females. Although the precise biological mechanisms underlying these observed sex differences remain largely unclear, there is compelling biological plausibility. For example, APOE may interact with estrogen through various pathways such that the presence of the ε4 allele exacerbates the female-specific effects of fluctuations/loss of estrogens during perimenopause and postmenopause on AD [64]. Alternatively, the observed sex differences in our sample may, in part, stem from a more pronounced selection bias among males. APOE ε4 has pleiotropic effects on cardiovascular disease and mortality, and males may have a higher risk of cardiovascular disease and mortality through APOE-related mechanisms and other pathways [19]. Our LASI-DAD sample is generally older and thus more likely to include healthier male ε4 carriers who demonstrate resilience against the detrimental ε4 effects on cognitive function and age-related diseases. Consequently, our study may underestimate the association between ε4 and cognition in males. Indeed, while our findings align with the majority of studies examining sex
differences, a few studies have reported conflicting findings [26,65]. For instance, a recent study in UK Biobank participants with white British ancestry found no significant interactions between \( \varepsilon 4 \) and sex on cognitive abilities [65]. Further investigation is required to elucidate the observed sex-specific \( \varepsilon 4 \) effects on cognitive function and dementia in diverse populations.

In our study, as expected, having at least some formal education was associated with better cognitive performance. However, this association did not differ statistically across education groups. Prior research evaluating this interaction in European ancestry samples has yielded conflicting results, with some studies demonstrating that higher education may counteract the negative effects of \( \varepsilon 4 \) on cognitive function and dementia [16,66]. Higher education may provide greater cognitive reserve, allowing individuals to better tolerate age- and dementia-related brain pathologies and maintain cognitive function, thereby mitigating genetic risk and postponing the clinical manifestation of dementia. While we found no evidence of interaction when including a cross-product interaction term between \( APOE \varepsilon 4 \) and >0 years of education, education-stratified analysis showed that the magnitude of the association between \( \varepsilon 4 \) and most cognitive measures trended greater in those who never attended school compared to those who did. Lack of significant interactions may have been due, in part, to education being analyzed using a dichotomous variable based on having ever attended school, as some prior studies have suggested that the interaction between \( \varepsilon 4 \) and education may be at the tertiary level [66]. Although we found no interaction between \( \varepsilon 4 \) and tertiary education, it is likely that we lacked statistical power to detect such an interaction due to the limited number of participants with tertiary education (n=95). Further, overall sample size may have limited our power to detect smaller effects. In addition, the complex social hierarchy and high levels of social stratification in India, which we are unable to completely capture, might also influence this interaction.
Sensitivity analyses support our main findings while additionally identifying an association between the $\varepsilon2/\varepsilon3$ genotype and lower visuospatial function compared to $\varepsilon3/\varepsilon3$. Despite mounting evidence suggesting a protective role of $\varepsilon2$ against AD, previous studies examining its effect on cognition have yielded inconsistent findings. For instance, one study found that $\varepsilon2$ carriers demonstrated worse performance in visuospatial attention in mid-adulthood [67], whereas another study in older Koreans without dementia showed that $\varepsilon2$ carriers performed better on visuospatial measures [68]. Additional research is needed to replicate our findings and elucidate the $\varepsilon2$ effect on cognitive function.

This study has some limitations. First, we were unable to reliably estimate the dosage effect of APOE $\varepsilon4$ due to the rarity of $\varepsilon4$ homozygotes ($n = 36$). Second, LASI-DAD only included participants aged 60 or older, which may have led to selection bias. Our results might underestimate the true association between $\varepsilon4$ and cognition since older adults carrying $\varepsilon4$ and with poorer cognitive function might be less likely to participate due to morbidity or death. However, $\varepsilon4$ allele frequency did not appear to decrease with age within our sample. This contrasts with findings from prior studies showing a decrease in $\varepsilon4$ frequency with increasing age [69,70]. Notably, our study identified a similar decreasing trend in $\varepsilon4$ up to age 85, at which point a subsequent increase was observed, which may be the result of underlying population structure differences or the small sample size of the oldest age groups. Third, despite adjusting for many potential confounders, there may be residual confounding from lifestyle factors and environmental toxicants. Fourth, all socioeconomic characteristics were self-reported and may be subject to response bias. Fifth, our study was cross-sectional with cognitive function assessed at a single time point. Consequently, we were unable to examine longitudinal $\varepsilon4$ effects. Future studies using longitudinal cognitive measures in LASI-DAD, which are currently being collected,
could provide further insights into the intricate interplay among ε4, sociodemographics, and cognitive aging in South Asians.

In conclusion, this is the first study to investigate the effect of APOE ε4 and its potential modification by sociodemographic factors on cognitive function in a nationally representative sample of older Indians. Our study provides important initial insights into the relationship between the strongest known genetic risk factor for AD and cognitive function in the South Asians population. Future research using longitudinal cohorts is warranted to provide a better understanding of the genetic influences on cognition and dementia within this genetically and socially diverse population.

Asterisk (*) denotes cognitive measures for which a statistically significant interaction term was observed.
Figure 1. Plots of significant two-way interactions between $APOE \varepsilon 4$ and age on cognitive measures. Predicted general cognitive function score (A), orientation score (B), and language/fluency score (C) of $APOE \varepsilon 4$ carriers and noncarriers are shown with standard error bars by age group. Cognitive measures are predicted using models adjusted for age (age >68), sex (male), state of residence, top 10 genetic PCs, education (upper secondary or vocational training and tertiary education), urban/rural residence, literacy, caste, quintiles of per capita household consumption, and $APOE \varepsilon 4 \times$ age >68 (Model 2). Color coding is according to age group.

Abbreviations: $APOE$ = apolipoprotein E; PC = principal components.
Figure 2. Plots of significant two-way interactions between $APOE \varepsilon 4$ and sex on cognitive measures. Predicted memory score (A) and language/fluency score (B) of $APOE \varepsilon 4$ carriers and noncarriers are shown with standard error bars by sex. Cognitive measures are predicted using models adjusted for age, sex (male), state of residence, top 10 genetic PCs, education, urban/rural residence, literacy, caste, quintiles of per capita household consumption, and $APOE \varepsilon 4 \times$ male (Model 2). Color coding is according to sex.
Abbreviations: $APOE =$ apolipoprotein E; PC = principal components.
