37

Abstract

38 Anxiety and depression commonly occur together resulting in worse health outcomes than when 39 they occur in isolation. We aimed to determine whether the genetic liability for combined anxiety 40 and depression was greater than when anxiety or depression occurred alone. Data from 12,558 41 genotyped twins (ages 38-85) were analysed, including 1,986 complete monozygotic and 1,809 42 complete dizygotic pairs. Outcomes were prescription of antidepressant and anxiolytic drugs, as 43 defined by the World Health Organization Anatomical Therapeutic Chemical Classification System 44 (ATC) convention, for combined anxiety and depression (n = 1054), anxiety only (n = 744), and 45 depression only (n = 511). Heritability of each outcome was estimated using twin modelling, and 46 the influence of common genetic variation was assessed from polygenic scores (PGS) for 47 depressive symptoms, anxiety, and 40 other traits. Heritability of combined anxiety and 48 depression was 79% compared with 41% for anxiety and 50% for depression alone. The PGS for 49 depressive symptoms likewise predicted more variation in combined anxiety and depression 50 (adjusted odds ratio per *SD* PGS = 1.53, 95% CI = 1.43-1.63; ΔR^2 = .031, ΔAUC = .044) than the 51 other outcomes, with nearly identical results when combined anxiety and depression was defined 52 by International Classification of Diseases (ICD) diagnoses (adjusted odds ratio per SD PGS = 1.70, 53 95% CI = 1.53-1.90; ΔR^2 = .036, ΔAUC = .051). Individuals in the highest decile of PGS for 54 depressive symptoms had over 5 times higher odds of being prescribed medication for combined 55 anxiety and depression compared to those in the lowest decile. We conclude that genetic factors 56 explain substantially more variation in combined anxiety and depression than anxiety or 57 depression alone. 58

69 Anxiety- and mood disorders are the most commonly occurring psychiatric disorders in the 70 general population, with lifetime prevalence estimates of up to 33.7% and 14.7%, respectively 71 (1,2). Symptoms of these disorder categories most often occur together, as evident by nearly half 72 of adults with anxiety also reporting depressive symptoms(3) and two-thirds of patients with a 73 primary diagnosis of major depressive disorder (MDD) also displaying pathological levels of 74 anxiety (4-6). It is of importance to distinguish between combined anxiety-depression and 75 anxiety or depression occurring alone because the combination has worse health outcomes, 76 entails greater risk of suicide, and is more resistant to treatment (7-9). Despite being highly 77 debilitating and prevalent, the heritability of this phenotype combination is largely unknown. 78 Hence, in the current study we aimed to determine whether the genetic contribution to 79 combined anxiety and depression differs from depression or anxiety alone. 80 81 Meta-analyses report twin-heritability in the range of 30-50% for separate occurrences of 82 anxiety- and depressive disorders (10,11), indicating a moderate heritable component. Although 83 the shared heritability between these disorder categories is known to be large (12,13), twin-84 studies on combined anxiety and depression are scarce. In a rare instance, Guffanti et al. (14) 85 estimated the heritability for sequential comorbidity of anxiety disorders and MDD in the range 86 of 53-57% using a relatively small sample of 545 high-risk participants from 65 87 multigenerational families. The findings by Guffanti et al. suggest that the combination of anxiety 88 and MDD might be more heritable than when each disorder occur alone, but the small sample 89 size together with the probable oversampling of cases warrants replication before firm 90 conclusions can be drawn. 91 92 Anxiety- and depressive disorders have also been predicted from polygenic scores (PGS)

that are based on genomic variations associated with phenotypes in independent discovery
samples (15). To date, anxiety PGSs explain about 0.5% of variance when predicting anxiety
disorders in independent cohorts (16,17), while depression PGSs explain 0.27-2.2% of variance

96 in depression (18,19). Tentative evidence further suggests that individuals with comorbid 97 anxiety have higher PGSs for a broad depression phenotype (odds ratio per SD PGS = 1.17) 98 compared to participants meeting only MDD criteria (20). These results have been corroborated 99 by recent findings, indicating that depression with comorbid anxiety, as defined by ICD codes, is 100 associated with higher polygenic load for several psychopathological traits in comparison with 101 depression without anxiety (21). Although these reports suggest increased genetic liability for 102 combined anxiety and depression compared to when anxiety or depression occur alone, the 103 limited number of studies and the differences in how cases have been ascertained, make 104 generalizable conclusions premature.

105

106 Electronic health-record based studies of genetic influences on anxiety and depressive 107 disorders commonly depend on diagnoses from specialist care. This could potentially induce a 108 bias in estimates of genetic liability as most individuals seeking treatment for anxiety or 109 depression initially consult a general practitioner in primary care, and often receive a drug 110 prescription from these practitioners without referral to a specialist. To include patients 111 seeking care for anxiety (*Anxiety-only*), depression (*Depression-only*), or both (*Combined* anxiety 112 and depression) from both primary and specialist care, we here used an algorithm to search the 113 Swedish Prescribed Drug Register for information about the symptoms for which drugs were 114 prescribed. This so-called dosage text is written by the GP and contains the main indication for 115 the drug prescription. To validate the ascertainment of cases, we compared which drug classes 116 were most commonly prescribed for each symptom category (Anxiety-only, Depression-only, 117 Combined anxiety and depression). In addition to symptom categories based on drug 118 prescription, outcome groups were also defined by International Classification of Diseases (ICD) 119 diagnoses that only included patients referred to specialist care. This allowed us to evaluate 120 whether genetic influences on outcome categories were dependent on the definition of cases 121 (ICD diagnoses vs. drug prescription information). Notably, the term combined here refers to 122 having been prescribed drugs for symptoms of anxiety and depression or diagnosed with a

123 depression and an anxiety diagnosis within a given time period without necessarily being

124 simultaneously present at any point in that time period (22).

125 For the purpose of this study, we constructed PGSs for 6 different traits focusing on anxiety, 126 depression, schizophrenia, and neuroticism, while also using 36 predefined PGSs from the 127 polygenic index repository (23). We then sought to understand how various PGSs could predict 128 categories of individuals prescribed medication for symptoms of anxiety, depression, or both. 129 This analysis could reveal whether a specific PGS shows an advantage in predicting symptom- or 130 disorder categories compared to other PGSs. It would also inform on whether one indication for 131 drug prescription (i.e., one symptom category) has more genetic liability over others. The 132 analyses were then repeated with outcomes defined by ICD diagnoses. By using a sample of 133 monozygotic and dizygotic twins from the Swedish Twin Registry, we could also determine if 134 there was a correspondence between genetic liability of outcomes estimated from PGSs and 135 heritability using classic twin modelling. 136 Another aim was to determine the effect of having extremely high or low PGSs on anxiety. 137 depression or combined anxiety and depression. We estimated risk carried by extreme PGSs by 138 comparing individuals in each decile with those in the lowest decile of the PGS distribution to 139 determine the utility of PGSs regarding risk stratification. 140 141 142 143 144 145 146

150		

Method

151 **Study population**

152 STAGE and YATSS are population cohorts of Swedish twins born between 1959-1985 and 153 1986-1992, respectively, that are part of the Swedish Twin Registry (24,25). The STAGE study 154 invited 25,364 twins to donate saliva for genotyping in 2005-2006, and 6,218 twins from YATSS 155 were invited in 2013-2014. Genotyping was performed on the 650K Illumina Global Screening 156 Array BeadChip for both cohorts in 2017-2019, resulting in a final sample of 13,699 twins with 157 genotype data available for 12,792 individuals. STAGE responders were representative of the 158 Swedish population in terms of educational attainment and family background characteristics 159 (26). 160

161 Measures

162 Anxiety and Depression Outcomes

163 We obtained drug prescription data for the entire study population from the Swedish 164 Prescribed Drug Register (27) through the Swedish Twin Registry (STR). We included N06AA 165 non-selective monoamine reuptake inhibitors, N06AB selective serotonin reuptake inhibitors 166 (SSRIs), N06AF monoamine oxidase inhibitors (non-selective), N06AG monoamine oxidase A 167 inhibitors, N06AX other antidepressants (which include certain selective serotonin and 168 noradrenaline reuptake inhibitors as well as other drugs), N05BA benzodiazepine derivatives, 169 N05BE azaspirodecanedione derivatives, R06A antihistamines for systemic use, C07AA beta 170 blocking agents (non-selective), and N03AX other antiepileptics (i.e., pregabalin) based on their 171 Anatomical Therapeutic Chemical code (ATC) (28). For the above-mentioned ATC-categories, we 172 employed an algorithm that searched through the prescription text, also known as the dosage 173 text, written by the prescribing physician. If the text included any of the words "worry", 174 "anxiety", "anxiety issues" (one word in Swedish "orosbesvär"), or "panic", the drugs were 175 classified as prescribed for symptoms of anxiety. For depression, one of the words "depression", 176 "depressive", "dejection" (i.e., "nedstämdhet" in Swedish), or "mood-enhancing" had to be

177 included in the text. The text-searching algorithm resulted in two columns for each drug, one 178 column for symptoms of anxiety and one for symptoms of depression, where individuals were 179 coded as 1 or 0 based on if the drug had been prescribed with or without the relevant target 180 words. Those without prescriptions of the target drugs were coded as NA and included as 181 controls. All drug prescriptions were treated as life-time events and there was no distinction 182 made between individuals prescribed drugs for anxiety and depression simultaneously, meaning 183 the terms occurred in conjunction in the dosage text, or individuals prescribed medication for 184 anxiety on one occasion and depression on another, meaning that the terms occurred in two or 185 more separate dosage texts. Based on the results from the text-searching algorithm, we 186 classified individuals into one of four categories, (1) if the text mentioned both anxiety and 187 depression they were included in the symptom category Combined anxiety and depression; (2) 188 if the text mentioned anxiety, but not depression, participants were included in the category 189 Anxiety-only; (3) if the text mentioned depression, but not anxiety, they were included in the 190 category Depression-only; (4) if the text did not mention anxiety or depression they were 191 categorized as *Medication-only*. The last group was included as the target drugs can be 192 prescribed for other indications than anxiety or depression (e.g., otherwise unspecified sleep 193 disorder, premenstrual syndrome, or adjustment disorder) and physicians sometimes omit 194 stating the indication that the medication is prescribed for. These symptom categories were 195 used as outcomes in subsequent statistical analyses, controls comprised those not included in 196 any of these categories.

We also obtained diagnoses from the National Patient Register, which are assigned by an
attending physician based on the International Classification of Diseases, eighth revision (ICD-8)
(1969-1986), ninth revision (ICD-9) (1987-1996), or tenth revision (ICD-10) (1997-present).
Similar to drug prescriptions, diagnoses were defined as life-time events and treated as binary
variables. Participants were categorized in the depression diagnosis group if they had any
depression-related ICD code, including 3004 (ICD-8), 300E, 311 (ICD-9), and F32-F39 (ICD-10).
Anxiety diagnosis was defined as having at least one of the following codes, 300 (excluding 3003,

204 3004) (ICD8), 300 (excluding 300D, 300E) (ICD-9), and F40-41 (excluding F41.2), F44-45, F48 205 (ICD-10). The F41.2 code was excluded from the anxiety diagnosis group, since it refers to 206 having symptoms of both anxiety and depression, but where neither is clearly predominant. 207 Participants with an F41.2 code were grouped in a third category (combined depression and 208 anxiety diagnoses), which also included those that had both a depression-related and an anxiety-209 related ICD code. These 3 groups (Combined anxiety and depression, Anxiety-only, Depression-210 only) were used as separate outcomes in subsequent analyses, in which controls included 211 participants that neither had a diagnosis nor been prescribed any antidepressants or anxiolytic 212 drugs.

213

214 Polygenic Scores (PGS)

215 A total of 42 PGSs were evaluated. Thirty-six of these came from the polygenic index (PGI) 216 repository, which contains scores derived from large-scale GWASs conducted in 23andMe, UK 217 Biobank (29), as well as other available datasets. For each phenotype, PGSs have been 218 constructed in 11 repository cohorts including the STR, with a leave-one-out approach to 219 distinguish the discovery sample from the target cohort. Hence, PGSs in STAGE and YATSS were 220 created from GWAS summary statistics that exclude these datasets, which allows for unbiased 221 targeting of phenotypes in our sample to test the predictive performance of PGSs from the PGI-222 repository. Information on quality control and PGS construction have been reported in detail 223 elsewhere (23).

In addition to the 36 PGSs from the PGI-repository, we constructed 6 PGSs based on
Lifetime Anxiety Disorder diagnosis (LAD; cases = 31977; controls = 82114), Major Depressive
Disorder (MDD; cases = 170756; controls = 329443), schizophrenia (SCZ; cases = 67390;
controls = 94015), Neuroticism scores (NEURO; *n* = 323415), the Generalized Anxiety Disorder
7-item scale (GAD-7; *n* = 126175), and the Patient Health Questionnaire-9 (PHQ-9; *n* = 126733).
The LAD-PGS was based on summary statistics from the meta-analysis performed by Purves et
al. (17), the MDD-PGS was based on summary statistics published in Wray et al. (19) and

231	Howard et al. (30), and the SCZ-PGS was created from summary statistics obtained from Ripke et
232	al. (31). The NEURO, GAD7, and PHQ9 PGSs were all based on individual level data from the UKB
233	(29,32). Ambiguous SNPs (alleles A/T or C/G), trivial SNPs (showed no variation across UKB)
234	and SNPs with a minor allele frequency (MAF) < 0.01 were all excluded. We used the LDAK
235	software (33) with the BLD-LDAK heritability model (34), where contribution of a SNP depends
236	on MAF, LD and functional annotations. PGS construction was performed with LDAK-Bolt-
237	Predict for individual-level data as well as LDAK-BayesR-SS for summary statistics, and was
238	limited to SNPs that overlapped between cohort genotype, UKB reference panel and GWAS
239	summary statistics. Finally, we converted all PGSs to <i>z</i> -scores for interpretation purposes.

240

241 Statistical analyses

242 *Twin heritability*

243 Twin heritability (h^2_{TWIN}) was estimated by fitting structural equation models that 244 decomposed variance in the outcome measures into additive genetic (A), common-245 environmental (*C*) and unique-environmental variance (*E*) as well as with models that only 246 estimated the A and E components. These models are based on the assumptions that 247 Monozygotic (MZ) and Dizygotic (DZ) twin pairs share common environmental effects to the 248 same extent and that MZ twins share 100% of their segregating alleles, while DZ twins share 249 50% of their segregating alleles. Thus, the additive genetic effects are shared with correlation 250 equal to 1 between MZ pairs and correlation 0.5 between DZ pairs. Analyses were initially 251 performed using only same sex twin pairs and were then repeated including DZ pairs with 252 different sexes in addition to same sex twin pairs. Due to the case/control design (i.e., binary 253 traits as outcome measures), we used the liability threshold model, which assumes a latent 254 bivariate normal distribution of the observed dichotomous variables (35,36). Model fit was 255 assessed by likelihood ratio tests (LRT) and Akaike's information criteria (AIC). All twin models 256 included sex and age as covariates. Twin heritability was analysed with the mets R-package (37).

258 **PGS prediction of anxiety and depression outcomes**

259 To determine effect sizes of PGSs in predicting each of the outcomes based on prescription 260 data (Combined anxiety and depression, Anxiety-only, Depression-only, Medication-only) or 261 diagnosis groups (Combined depression and anxiety diagnoses, anxiety diagnosis, depression 262 diagnosis), we used logistic regression. Effect sizes are presented as adjusted odds ratios (OR) 263 per SD PGS, with 95% confidence intervals (95% CI) for each outcome. Pseudo- R^2 (Nagelkerke 264 R^2) was estimated for the full model (all covariates including PGS) and the base model (not 265 including PGS). The latter included sex, age, zygosity (to correct for clustering of family 266 members), the first 20 ancestral principal components (to control for population stratification), 267 and cohort (STAGE, YATSS) as covariates. Proportion of predicted variance was calculated as the 268 difference between the two pseudo- R^2 estimates (ΔR^2). We also calculated area under the 269 Receiver operating characteristics curve (AUC) between the base model and the full model 270 including the best performing PGS. 271 We next included all PGSs in one regression model to assess the ability of each score in

predicting the outcomes while controlling for the other PGSs, and evaluated the ΔR^2 to assess how much variance in outcomes could be predicted when all genetic indices were included in the same model. Collinearity diagnostics showed that all variables had a variance inflation factor and tolerance statistic well below 10 and above 0.1, respectively, indicating no significant multicollinearity.

To describe associations across the PGS distribution with each outcome, we first selected the PGSs that had the overall strongest association with the outcomes according to their OR and *p*-value, and divided the sample in deciles based on their PGS. Using logistic regression, we computed the association between each outcome and the highest PGS decile compared with the remaining 80% of the sample (leaving out the bottom 10%). The same analysis was performed for the lowest decile (leaving out the top 10%). These analyses inform on how groups with extreme scores compare with those that have scores closer to the mean. To assess the

284 incremental increase in association between PGS and each outcome across deciles, separate

regression analyses were performed for each decile using the lowest as reference.

All *p*-values were corrected for multiple comparisons using the Benjamini-Hochberg

287 procedure (38) for False Discovery Rate (FDR < .05).

- 288
- 289

Results

290 Sample characteristics

291 Data on drug prescription were retrieved for 13699 individuals, where genotype 292 information was available for 12792 participants (see Table 1 for sample characteristics). Due to 293 missing data for sex and age, the final sample for PGS-predictions using regression models with 294 covariates included 12558 individuals, whereas twin heritability analyses were based on 1986 295 complete MZ-pairs and 1809 DZ-pairs. The control group for analyses of prescription-based 296 outcomes include all individuals without any prescriptions of the target drugs, while analyses of 297 diagnostically defined outcomes included those without drugs or diagnoses in the control group 298 (see supplemental material for the exact *n* in each analysis).

(see supplemental material for the exact *n* in each analysis).

To compare patterns of prescriptions across outcome groups, we computed the proportion of individuals in each group that were prescribed medications from the drug classes N06AA-AB,

301 N06AC-AX, benzodiazepines, antihistamines and Buspirone/Propranolol/Pregabalin

302 (BusProPre) (Fig. 1). In the Anxiety-only category, drugs from the class antihistamines were

303 most frequently prescribed, followed by N06AA-AB and benzodiazepines. In contrast, the

304 Depression-only group had the lowest proportion of prescriptions from the benzodiazepine

305 class compared to any of the other groups. Instead, N06AA-AB was the most commonly

306 prescribed drug class for this group followed by N06AC-AX. The Combined anxiety and

307 depression group had high prescription rates of drugs from the classes N06AA-AB and

308 antihistamines as well as benzodiazepines and N06AC-AX. Notably, individuals in the Combined

309 symptom category were on average prescribed drugs from more drug classes (2.89) compared

to any of the other outcome groups (1.28-1.88). The Medication-only group had the lowest rates

of prescriptions (1.28) with antihistamines being the most frequently prescribed, followed by
N06AA-AB and BusProPre. These results indicate that the prescription text that was used for
categorizing individuals into the outcome groups was associated with different treatment
decisions.

315 To assess diagnoses of anxiety and depressive disorders, we retrieved data from the 316 National Patient Registry. Out of the 1029 participants with an ICD code associated with these 317 disorders, 379 had only a depression diagnosis, 283 had only an anxiety diagnosis, and 367 had 318 combined depression and anxiety diagnoses. The group with combined anxiety and depression 319 diagnoses consisted of 173 individuals that had both a depression- and an anxiety-related ICD 320 code, 40 individuals with an F41.2 (mixed anxiety and depressive disorder) diagnosis, 50 321 individuals with F41.2 and an anxiety ICD code, 27 individuals with F41.2 and a depression ICD 322 code, and 77 individuals with F41.2 plus a depression and an anxiety ICD code. As expected, the 323 number of individuals with diagnoses were fewer than the number of individuals with 324 prescriptions, as most individuals receiving prescriptions from primary care are not referred to 325 a specialist that enters a diagnosis in the Swedish patient registry.

326

327 Twin-based heritability of anxiety and depression

The additive genetic influence on having been prescribed medication for combined anxiety and depression was $h^{2}_{TWIN} = 0.79$ (95% CI = 0.71-0.86). Lower additive genetic effects were found for having been prescribed medication for Anxiety-only ($h^{2}_{TWIN} = 0.41$, 95% CI = 0.23-0.60) or Depression-only ($h^{2}_{TWIN} = 0.50$, 95% CI = 0.26-0.75). Further, having been prescribed the same drugs, but without an indication of anxiety or depressive symptoms, resulted in a heritability estimate of $h^{2}_{TWIN} = 0.29$ (95% CI = 0.17-0.40). See supplementary Table S1 for twinmodel estimates.

- 335
- 336
- 337

338 **Prediction of anxiety and depression from PGSs**

339 Regression models with single PGS predictors

340 Figure 2 shows which PGSs that were significantly associated with the different outcomes, 341 and the strength of associations in terms of OR per SD PGS. When modelled as individual 342 predictors, 27 out of the 42 PGSs evaluated (36 from the PGI repository and 6 scores computed 343 for the purpose of this study) showed a significant increase in predicting drugs prescribed for 344 Combined anxiety and depression compared with the base model (base model $R^2 = .041$, AUC = 345 .632). Out of these 27 PGSs, the PGS for depressive symptoms from the PGI repository (DEP-346 PGS) was the strongest predictor ($\Delta R^2 = .031$, $\Delta AUC = .044$, OR = 1.53, 95% CI = 1.43-1.63) followed by the PGS for major depressive disorder (MDD-PGS) computed from Wray et al. (19) 347 348 using LDAK (ΔR^2 = .020, ΔAUC = .032, OR = 1.39, 95% CI = 1.30-1.49), PGS for Subjective 349 Wellbeing (SWB-PGS; $\Delta R^2 = .018$, $\Delta AUC = .028$, OR = 0.73, 95% CI = 0.68-0.78), Lifetime Anxiety 350 Disorder (LAD-PGS) computed with LDAK ($\Delta R^2 = .015$, $\Delta AUC = .022$, OR = 1.33, 95% CI = 1.25-351 1.42), PGS for Self-rated Health ($\Delta R^2 = .014$, $\Delta AUC = .021$, OR = 0.75, 95% CI = 0.70-0.80), and 352 PGS for neuroticism computed with LDAK ($\Delta R^2 = .013$, $\Delta AUC = .020$, OR = 1.30, 95% CI = 1.22-353 1.39). The pattern of results was similar for the other outcomes, with DEP-PGS being the best or 354 second-best predictor, but the predictive performance of PGSs was markedly reduced as 355 indicated by lower R² values and lower ORs per SD PGS (Tables S3-S4 and Figure 2). The mean 356 value of DEP-PGS (z-scores) in the Combined anxiety and depression group (mean = 0.33) was 357 almost double the mean value in the Depression-only (mean = 0.17) and Anxiety-only (mean = 358 0.16) groups. For comparison, mean values were 0.09 in Medication-only, and -0.08 in the non-359 medicated control group. One-way ANOVA [F(4, 12787) = 54.63, p < 2e-16] followed by post-hoc 360 tests, showed that DEP-PGS was on average significantly higher in each outcome group 361 (Combined anxiety and depression, Anxiety-only, Depression-only, Medication-only) compared 362 with the non-medicated control group. However, the Combined anxiety and depression group 363 also had significantly higher mean DEP-PGS as compared to the other outcome groups,

364 indicating that this is a disorder combination with higher polygenic load than anxiety or

365 depression alone (see Supplemental Table S2 for results of post-hoc tests).

366 Clinical Diagnoses Regressed on Individual PGSs. To validate case classifications based 367 on drug prescriptions, the regression analyses with PGSs as individual predictors were repeated, 368 but this time with the clinical diagnosis groups as outcomes. For the combined depression and 369 anxiety diagnoses group (base model $R^2 = .047$, AUC = .667), DEP-PGS was the strongest 370 predictor (ΔR^2 = .036, ΔAUC = .051, OR = 1.70, 95% CI = 1.53-1.90) followed by SWB-PGS (ΔR^2 = 371 $.030, \Delta AUC = .048, OR = 0.61, 95\%$ CI = 0.55-0.68) and MDD-PGS ($\Delta R^2 = .026, \Delta AUC = .038, OR = .038, OR$ 372 1.59,95% CI = 1.43-1.77). When predicting the probability of having an anxiety diagnosis (base 373 model R^2 = .032, AUC = .644), LAD-PGS (ΔR^2 = .013, ΔAUC = .022, OR = 1.41, 95% CI = 1.25-1.60), 374 DEP-PGS (ΔR^2 = .013, ΔAUC = .016, OR = 1.40, 95% CI = 1.23-1.58) and MDD-PGS (ΔR^2 = .012, 375 $\Delta AUC = .018$, OR = 1.39, 95% CI = 1.23-1.57) emerged as the top predictors. For the depression 376 diagnosis group (base model R^2 = .026, AUC = .631), DEP-PGS (ΔR^2 = .015, ΔAUC = .028, OR = 377 1.41, 95% CI = 1.27-1.57), MDD-PGS (ΔR^2 = .015, ΔAUC = .022, OR = 1.40, 95% CI = 1.26-1.55) 378 and SWB-PGS ($\Delta R^2 = .014$, $\Delta AUC = .029$, OR = 0.71, 95% CI = 0.64-0.79) were the PGSs with the 379 strongest predictive performance (see suppl. Tables S5-S6 for OR, R², N, and p-values for PGSs 380 predicting ICD diagnoses outcomes). DEP-PGS had the overall highest accuracy and predicted 381 more variation in the combined anxiety and depression diagnoses group compared with those 382 having only one of these diagnoses, which is consistent with results from the regression analyses 383 with symptom categories defined by drug prescription (see Figure 3). Hence, subsequent 384 analyses include only prescription-based symptom categories as outcomes, since they include 385 more cases than the diagnostically defined groups.

386 *Regression models with multiple PGS predictors*

387 In a single regression model containing all 42 PGSs simultaneously (base model $R^2 = .041$,

388 AUC = .632), only DEP-PGS (OR = 1.23, 95% CI = 1.12–1.35), SCZ-PGS (OR = 1.18, 95% CI = 1.10–

- 389 1.27), and MDD-PGS (OR = 1.14, 95% CI = 1.06–1.24) remained significantly associated with
- drug prescription for Combined anxiety and depression ($\Delta R^2 = .057$, $\Delta AUC = .071$). When

391	predicting prescriptions for Anxiety-only (base model $R^2 = .023$, AUC = .605), again using all 42
392	PGSs ($\Delta R^2 = .034$, $\Delta AUC = .057$), the only significant predictors were SelfHealth-PGS (OR = 0.800,
393	95% CI = 0.72–0.89) and SCZ-PGS (OR = 1.15, 95% CI = 1.05–1.25). When predicting drug
394	prescription for the Depression-only group ($\Delta R^2 = .031$, $\Delta AUC = .046$) and the Medication-only
395	group ($\Delta R^2 = .017$, $\Delta AUC = .025$), no PGS-predictor survived the correction for multiple
396	comparisons (see suppl. Tables S7-S8 for R^2 , OR and <i>p</i> -values). These results indicate that using
397	multiple PGSs in the same model improves prediction compared to using individual PGSs, but
398	that only a few PGSs have a unique contribution. Also, SCZ-PGS seem to have a unique
399	contribution to the genetic influence on the Combined anxiety and depression and Anxiety-only
400	categories although not being among the top 5 predictors in the regression models using single
401	PGSs.
402	To check for possible confounding of zygosity, the sample was split by kinship and all
403	regression analyses were repeated on the subsamples, with no substantial difference in the
404	pattern of results compared to findings based on whole-sample analyses (see suppl. Tables S9-
405	S16 for regression model estimates on split-half samples with no kinship).
406	
407	Outcome associations across the PGS distribution
408	We next wanted to know how extremely high or low PGSs predict drug prescription, as this
409	could indicate whether scores could be useful to identify groups of vulnerable individuals. The
410	highest and lowest deciles of DEP-PGS, the overall best performing genetic index, were
411	compared with the middle 80% of the sample to estimate ORs. Individuals in the top 10% had
412	greater odds of being prescribed medication for Combined anxiety and depressive symptoms
413	(OR = 2.02 , CI95% = 1.67 - 2.42), while those in the bottom 10% had a decreased risk (OR = 0.37 ,
414	

415 continuum carry genetic risk or resilience compared to the rest of the distribution (see

416 regression model estimates for all outcomes in suppl. Table S17).

417	To evaluate whether polygenic risk increased linearly across deciles in the distribution, we
418	computed the OR for each decile compared to the lowest decile. We found a cumulative increase
419	in OR with each decile for DEP-PGS (Figure 4 and suppl. Table S18). These results confirm to
420	expectations from an additive infinitesimal model. The largest OR was found when comparing
421	the lowest and highest deciles of the DEP-PGS (OR = 5.35, 95% CI = 3.78-7.73) in predicting
422	prescription-based symptoms of Combined anxiety and depression.

444

Discussion

445 Using polygenic scores and classical twin models, we investigated genetic influences on 446 prescription of antidepressant and anxiolytic drugs for combined anxiety and depression 447 relative to indications of anxiety or depressive symptoms only. Heritability was 79% for 448 combined anxiety and depression, which was larger than for anxiety or depression alone, and is 449 on par with heritability estimates for schizophrenia (39) and bipolar disorder (40). Combined 450 anxiety and depression was also the outcome most strongly associated with PGSs, indicating that 451 SNP-based prediction concurred with twin-based heritability estimates. These results were 452 corroborated by PGSs more accurately predicting combined clinical depression and anxiety 453 diagnoses compared with those having only a depression or an anxiety diagnosis. Thus, the 454 results from two complementary methods to evaluate genetic influence, and two different case 455 classification approaches, indicate a stronger genetic influence on the Combined symptom 456 category than on anxiety or depressive symptoms alone.

457

458 It is well-known that the combination of anxiety and depressive symptoms is more 459 impairing and difficult to treat than each symptom category alone (7–9). Despite this knowledge, 460 the aetiology of this phenotype combination is poorly understood, and our study represents one 461 of the few attempts made to investigate its genetic basis. There is evidence that the shared 462 genetic component between anxiety and depression is substantially larger than the unique 463 contributions to any of these phenotypes on their own. Large scale GWASs have found robust 464 genetic correlations in the range of 80-95% (16,17), with 99% of risk variants for anxiety also 465 influencing depression and 73% of risk variants for depression also conferring liability to 466 anxiety (21). A conclusion from these findings is that the genetic influence on anxiety and 467 depression is best explained by a common genetic factor. Accordingly, the fraction of unique 468 variants that influence each phenotype could, when combined, only represent a small portion of 469 the increase in genetic liability between the Combined anxiety and depression outcome 470 compared to Anxiety- or Depression-only outcomes. An important consideration is that the large

471 genetic overlap between anxiety and depression has been estimated in GWASs employing 472 minimal phenotyping approaches that do not consider phenotypic heterogeneity (18). Recent 473 findings based on more refined phenotyping showed that MDD with comorbid anxiety was twice 474 as heritable compared to a broadly defined depression phenotype (41), indicating that there 475 may be unique subsets of genetic variants associated with certain disorder subtypes not 476 captured by previous GWASs. Thus, performing a large scale GWASs of the Combined anxiety 477 and depression symptom category could be of value, as it would probably increase the predictive 478 power of PGS predictions and help to tease out whether loci associated with this phenotype 479 combination differs from MDD or anxiety disorders alone.

480

481 In line with the reported large genetic correlations between anxiety and depression 482 (16,17,21), PGS for depressive symptoms predicted Anxiety-only to the same extent as 483 Depression-only. The same pattern emerged for the PGS for lifetime anxiety diagnosis (LAD-484 PGS) that did not predict anxiety better than depression. PGSs for psychiatric disorders (anxiety, 485 depression, schizophrenia, and ADHD) were however better at predicting anxiety, depression 486 and their combination than were PGSs for physical disorders, body length or consumption of 487 alcohol or marijuana. PGSs for subjective wellbeing and cognitive measures in turn predicted 488 resilience. When controlling for all PGSs, the PGS for schizophrenia emerged as a significant 489 predictor for the Anxiety-only and Combined symptom categories, suggesting that this PGS 490 includes unique risk variants common to several disorders.

491

The finding of a distinction between the genetic contribution to combined anxiety and
depressive symptoms relative to their isolated manifestations could reflect a more general
genetic liability for psychopathology. In a meta-analysis across eight disorders, the Cross
Disorder Group of the Psychiatric Genomics Consortium found 109 pleiotropic loci associated
with two or more disorders (42), which extends previous results of shared common variant risk
across schizophrenia, MDD, bipolar disorder, anxiety disorders, and ADHD (43). Thus, the high

498 degree of genetic overlap among psychiatric disorders suggests that clinical classifications of 499 discrete disorder categories do not reflect distinct underlying processes at the genetic level. A 500 dimensional account of psychopathology has suggested that most common psychiatric disorders 501 are unified by a single transdiagnostic dimension representing lesser-to-greater severity of 502 psychopathology, referred to as the p-factor (44). Combined anxiety and depression represent 503 greater severity than anxiety or depression alone, and the stronger genetic influence on the 504 Combined anxiety and depression outcome could be a result of a genetic factor that makes 505 individuals prone to developing psychiatric illness in general (45). Extending this line of thought 506 to other psychiatric diagnoses, it could be predicted that the combination of any two diagnostic 507 or symptom categories would be associated with greater heritability than each diagnosis in 508 isolation. This hypothesis could be tested in future research.

509

510 Increasing the predictive performance of PGSs is important for risk stratification. We 511 employed AUC estimates to index how well PGSs discriminated between participants with or 512 without depression and anxiety. Participants with combined depression and anxiety determined 513 from prescription data were distinguished from participants without depression or anxiety with 514 an AUC of 68% (i.e., 18% above chance level of 50%) based on DEP-PGS, sex, age and ancestral 515 principal components. The DEP-PGS by itself contributed 4.4% to the overall classification 516 accuracy of the model. When Combined depression and anxiety was defined by ICD diagnoses 517 instead of from prescription data, the AUC was 72% (5.1% unique contribution by DEP-PGS). An 518 AUC of 70% is generally considered fair (46) and a 4-5% increase in overall accuracy solely 519 based on one polygenic score is an important improvement in predictive performance, but 520 questionable for the purpose of risk screening in the general population. To determine a cut-off 521 in terms of AUC for when predictive factors should be implemented in screening and preventive 522 treatment efforts is complex and depends on factors such as patient benefits, costs for the health 523 care system and eventual risks associated with the intervention. For comparison, population 524 screening for adverse childhood events, a well-known social risk factor for psychiatric disorders

525 (47-49) is already underway in the USA where individuals with high scores on an adverse 526 childhood events inventory are referred for health interventions (50). Adverse childhood event 527 scores have been shown to predict anxiety with an AUC ranging from 54% to 59%, and 528 depression with an AUC between 57% and 62% depending on whether adverse childhood 529 events were assessed prospectively or retrospectively (51) which underscores that even modest 530 AUCs can justify interventions if the patient benefits are judged to be large enough. Thus, if PGSs 531 predicting anxiety and depression in the future also can be shown to predict responses to 532 preventive interventions, they could be useful in guiding treatment decisions to improve patient 533 health. We further foresee that PGSs are likely to complement other features in panels of 534 prognostic markers as their predictive performance will increase. 535

536 The study had limitations. Depression related PGSs were based on larger discovery samples 537 than anxiety-related scores, which impacts the results, as the out-of-sample predictive 538 performance of a PGS is dependent on the definition of the phenotype and size of the discovery 539 sample (20). Therefore, predictive performance will likely increase with larger samples and 540 combined with more refined phenotyping. Outcomes were based on symptom categories and 541 treated as life-time events. Consequently, we do not know if individuals' anxiety and depression 542 co-occurred or whether they were separated in time in the group with combined anxiety and 543 depressive symptoms. In either case, our results point to the increased genetic propensity of 544 having been prescribed drugs for combined anxiety and depressive symptoms or having been 545 diagnosed with both disorders in a clinical setting.

546

547 In conclusion, we report larger genetic influence on combined anxiety and depressive 548 symptoms than on either symptom category alone. A tentative explanation could be that 549 depression and anxiety can be described by one latent variable and that increasing severity 550 along this latent variable is associated with increased genetic liability.

Table 1. Sample Characteristics.

Variable	Description	N	%, x̄ (SD, range)	N06AA-AB	N06AC-AX	Benzo	Antihis	BusProPre	x drugs prescribed	
Sample	Total	13699	100%	2425	1140	1064	2133	620	0.54	
Sex	Female	7939	58.00%	1830	788	780	1664	458	0.70	
	Male	5087	37.10%	595	301	284	469	162	0.36	
Age	Age at final data extraction (2023)	13026	51.69 (7.87. 38-85)	-	-	-	-	-	-	
Zygosity	Complete MZ	3972	28.99%	695	273	297	655	159	0.52	
	Complete DZ same sex	1732	12.64%	305	128	143	262	86	0.53	
	Complete DZ diff. Sex	1886	13.77%	253	145	111	223	67	0.42	
	No kinship	6109	44.60%	1172	594	513	993	308	0.59	
Outcomes	Combined Anxiety and Depression	1054	7.07%	978	591	499	784	190	2.89	
	Anxiety only	744	4.99%	357	134	307	500	99	1.88	
	Depression only	511	3.43%	448	205	44	126	38	1.68	
	Medication only	1630	10.93%	642	210	214	723	293	1.28	

739

741 *Note.* BusProPre = Buspirone or Propranolol or Pregabalin; Benzo = Benzodiazepines; Antihis = Antihistamines; N06AA = non-selective monoamine reuptake inhibitors; N06AB = selective serotonin reuptake inhibitors; N06AC-AX = monoamine oxidase inhibitors (non-selective), monoamine oxidase A inhibitors, other antidepressants. No kinship = individuals without sibling in data set due to missing genotype information.

745 746

Note: N06AA-AB = non-selective monoamine reuptake inhibitors, selective serotonin reuptake
 inhibitors (SSRIs); N06AC-AX = monoamine oxidase inhibitors (non-selective), monoamine oxidase A
 inhibitors, other antidepressants (which include certain selective serotonin and noradrenaline reuptake

inhibitors as well as other drugs); Benzo = benzodiazepine derivatives; BusProPre = Buspirone,
 Propranolol, Pregabalin. Drug classifications are based on their Anatomical Therapeutic Chemical
 code (ATC).

Figure 2. Adjusted OR per SD increase in PGSs predicting prescription-based outcomes. Error bars represent 95% CI.

Figure 3. Genetic liability for anxiety and depression outcomes. (A) Twin heritability for each outcome (AE-model), error bars represent 95% CI. (B) Accuracy (ΔR^2) of depressive symptoms PGS (DEP-PGS) from the Polygenic Index Repository in predicting each outcome above the baseline model.
