(Dated: July 22, 2024)

We search for correlations in the preferences for seasonal time arrangements across different countries. With this purpose we analyze the public consultation on summertime arrangements (Daylight Saving Time) launched by the European Commission in 2018 (the largest sample size study of this kind, 4.55 million replies, median shares of population per Member State 0.366 %). We also analyze the starting point of human activity in Europe from the Harmonized European Time Use Survey, also the largest scale survey to assess the budget of time in modern societies.

We find that the shares of population willing to abolish the seasonal regulations of time increases with increasing latitudes and with delayed winter sunrise times. Notably the distance of the winter sunrise to the starting point of human activity plays a determining role in predicting the preferences ($R^2 = 0.7; p = 2 \times 10^{-5}; N = 17$ Member States). We provide a simple physiological rationale for this finding.

Our results challenge the current prevailing point of view on clock regulations that associates them to energy saving only, and unveil the physiological roots of these regulations.

Daylight Saving Time (DST) or summertime arrangements is the practice by which many Extratropical (chiefly Western) societies bound to pre-set schedules have successfully regulated their starting times through seasons. The practice consists in a one-hour delay of clock time in autumn followed by a backward one-hour advance of clock time in spring. The shifts imperfectly follow the delay (autumn) and the advance (spring) of sunrise times. All else equal, it is equivalent to a seasonal regulation of the pre-set schedules so that the phase of human activity is bimodal: delayed in winter, advanced in summer because 8am DST is just an alias for 7am ST (standard time), the hour preceding 8am ST.

The arrangements aimed to solve a tricky social question that roots on human physiology and on environmental conditions. How can pre-set schedules conciliate

with the irregular distribution of sunrise times? Which is the best hour of the day for a pre-set starting time in view of the span of sunrise times? How can pre-set starting times be best aligned to sunrise time from winter to summer? The original sponsors of clock regulations focus on "the alignment of work hours closer to sunrise and greater use of outdoor recreation in the [spring and summer] evening"(Harrison, 2013, Introduction), see also Hudson (1895, 1898); Pollack (1981); Willet (1907). We note all these questions are associated to one and only environmental variable: the latitude.(Martín-Olalla, 2019a, 2022)

DST regulations have been long time under public scrutiny(Monk and Folkard, 1976) due to the acute impact that the stroke of one hour brings in health and societal issues, specifically in traffic accidents(Coren, 1996; Fritz *et al.*, 2020) and myocardial infarctions(Janszky and Ljung, 2008), and of the disruption of the seasonal adjustement(Kantermann *et al.*, 2007). Some review studies have also put emphasis on the chronic circadian misalignment that the practice might bring(Johnson and Malow, 2022; Roenneberg *et al.*, 2019a) and have flagged the practice as "artificial". With tiny, unspecific energy savings as the only potential benefit of seasonal DST, many physiologists and some medical societies have built a strong case against the practice and demand decision makers to cancel it(e Cruz *et al.*, 2019; Malow, 2022; Rishi *et al.*, 2024; Roenneberg *et al.*, 2019b; Watson, 2019).

The understanding of social preferences for seasonal DST and for permanent DST has also become recently a point of interest in this field. Surveys usually show a majority of respondents pro canceling the biannual change of clocks, which is celebrated by those who sponsor the abolishing of clock regulations. But polls also show a majority pro setting DST permanently, in bold disagreement with the "science-informed" positions that favor permanent ST(Antle *et al.*, 2022; Coogan *et al.*, 2022; Rubin, 2023).

This work aims to identify the best explanatory variable that predicts the preferences for cancelling of the biannual changing of the clocks. We present a thorough analysis of the public consultation that the European Commission launched in 2018 on summertime arrangements, and whose results prompted the Commission to demand the cancelling of DST, without success. The analysis will cross-correlate the preferences for abolishing DST with latitude, and with human activity deduced from the Harmonized European Time Use Survey (HETUS)(Eurostat, 2010).

The 2018 public consultation was a self-reported study, without sample design but with a large number of replies. Question 2 is the focus of our study: the individual preference *to keep or to abolish the current arrangement?* [seasonal DST]. This question provides a feedback on the *statu quo* under which the respondent has been living in the recent past. In all but two Member States (Greece

and Cyprus) the majority of respondents supported the abolish choice. The Commission committed to this result and demanded the abolition, without success.

For our study the shares of respondents by Member State against or pro the current regulations and their net balance are irrelevant. Instead, we will focus in the *shares of population* against and pro the current regulations that the public consultation was able to get. Although the lack of sample design may have turned this metric prone to many confounding, uncontrolled factors, this study will show that human physiology also impacted the results in a strong, prescribed, controlled way. We will show that the shares of population against DST regulations correlated with the latitude and that they can be best explained by the shares of early risers (those who start their activity earlier than the winter sunrise time). Not surprisingly, they are the very same explanatory variables that gave rise to DST regulations in the early 20th century. Therefore our study highlights the role of human physiology and environmental conditions (latitude) in this issue, and challenge both the association of DST with longitude/time zones(Johnson and Malow, 2022; Roenneberg *et al.*, 2019b) and the public policies that call for one-size-fits-all solutions.

Three major strengths of the study must be highlighted: first the large number of countries involved — from 25 to 17, depending of the analysis— which brings the association between explanatory variables (latitude and human activity) and the outcome (preferences to abolish DST) statistically significant. Second, the large sample size of the public consultation: the median value of the distribution of turn-outs per Member State was $0.367\,\%$ of the population, much larger than a standard poll and much larger than other web-based, self-reported studies like Kantermann *et al.* (2007) with $55\,000$ respondents in Central Europe. Third, the wide range of latitudes that allocates the different Member States —from $35°$ to $63°$ and beyond— which brings vividly different seasonal cycle of light and dark, under the same clock regulations, and give support to the correlation. Previous studies on the association between DST preferences and latitude were limited to one country (Norway(Bjorvatn *et al.*, 2021)) and one province (Alberta, Canada(Antle *et al.*, 2022)), both with a narrower range of latitude.

## 1. RESULTS

### 1.1. How public the consultation preferences associate with the geographical predictors

We first show the association between the geographical predictors (details in Section 3.1) and the results of the 2018 public consultation on DST (outcome, details in Section 3.2). On the first hand, we consider two outcomes: the shares of respondents willing to cancel DST,

hereafter $C$, by Member State; and the shares of respondents willing to keep DST, hereafter $K$. On the other hand, we consider four predictors. First we test the longitude $\lambda$ and the time offset —the distance from solar noon to clock midday. Neither of these two predictors sets seasonal variability and therefore neither should set preferences for neither outcome.

Indeed, the null hypothesis "the shares of respondents pro canceling $C$ or pro keeping $K$ DST by Member State do not depend on the longitude or the time offset" sustained ($p = 0.185; p = 0.245; p = 0.675; p = 0.927$) at the standard level of significance ($\alpha = 0.05$), see Table S4 and Figure S1 in the Supplemental Information.

We then considered the latitude $\phi$ as a predictor, and found that that the null hypothesis does not sustain ($p = 0.043; R^2 = 0.166; N = 25$) for the abolish outcome. The association brings larger shares of respondents willing to cancel DST with higher latitude. On the contrary, the null hypothesis sustains for the keep outcome ($p = 0.449$).

Finally, we tested the winter sunrise time $6\,\text{h} + F(\phi)$, where $F(\phi)$ is the seasonal factor, see Section 3.1 for a definition. We found that the null hypothesis does not sustain ($p = 0.015, R^2 = 0.231, N = 25$) for the abolish choice. Preferences for canceling DST increased with delayed sunrise times and larger seasonal variability, in line with previous expectations(Martín-Olalla, 2019a). On the contrary the null hypothesis sustained ($p = 0.666$) when the keep choice was tested. Figure 1A shows a scatter plot of $C$ versus the winter sunrise time with horizontal lines signaling the low and high quartiles of the distribution by Member State and Figure 1B does the same for the shares $K$.

Germany, Austria and Luxembourg shares met standard criteria for outlier identification and were removed from these associations, see inset in Figure 1 and section 3.2 for details. For the keep choice Cyprus shares were also qualified as an outlier and were removed from the bivariate analysis. In the end, the sample size was 960 199 replies (median shares 0.311 %) in 25 member states (against) and 174 489 (median shares 0.050 %) replies in 24 member states (keep).

We bring the attention to the pivotal role played by physical geography in the statistical significance in the $C$ versus winter sunrise time association. The range of the predictor extends for two hours, larger than the size of the DST shift.

## 1.2. How the public consultation preferences associate with human activity related predictors

To understand the interplay between the shares of population against DST, environmental factors and human physiology we now analyze their association with the human activity (see Section 3.3). The data set is here re-duced to the $N = 17$ participants in HETUS that also participated in the 2018 public consultation and were not flagged as outliers. The number of replies adds up 813 564, with median shares per Member State 0.311 %.

We did not find any statistically significant association between $C$ and the sleep/wake cycle or the work cycle when their parameters are measured by a distance to noon (either clock time or mean solar time). This is in line with our previous expectations because clock time and mean solar time are not impacted by seasons or latitude.

On the contrary, we did find a statistically significant association when the distances of the midpoints of the sleep/wake cycle and the work cycle to the winter sunrise time were tested. For the association between the sleep/wake cycle with $C$ we found $p = 0.006; R^2 = 0.41$; while for the labor cycle we found $p < 7 \times 10^{-4}; R^2 = 0.54$. Either of the two activities finds larger shares of population willing to cancel DST with earlier midpoints, shown by the negative value of the bivariate slope; see Table S3 in Supplemental Information.

In line with the goals of DST, which aims to regulate starting times, we analyzed the association between $C$ and morning time marks —sleep offset and work onset—. We found similar results (see Table S5 in Supplemental Information). Notably the consultation results correlate the more against the morning time marks for both activities. The association between $C$ and the time distance between work onset and the winter sunrise time finds $R^2 = 0.71$ and $p = 2 \times 10^{-5}$.

These results improve the results obtained when the shares $C$ were tested against the latitude ($p = 0.010$) and the winter sunrise time ($p = 0.004$) in this subset of $N = 17$ Member States.

Figure 2 shows in four panels the association between the morning timemarks (left) and midpoints (right) with the shares of population willing to cancel DST as per the public consultation. The top two panels refer to the sleep and other cares activity: sleep offset (left) and sleep midpoint (right). The bottom two panels refer to work onset (left) and work midpoint (right). The solid line shows the regression and the dashed lines bound the 95 % prediction interval associated with the regression.

## 1.3. Statistical significance of the correlations

The 2018 public consultation was a natural experiment driven by a self-reported study where "the respondents had to give very little information about themselves."(for Mobility and Transport, 2019, Section 3) The results were only disaggregated by Member State and the final report on the public consultation reads: "caution needs to be taken for the interpretation of the data in terms of causality and one needs to remember that the results are not [statistically] representative. This is why *only*

Figure 1 **A**. The association between the winter sunrise time $6\,\mathrm{h} + F(\phi)$ (solar time) and the shares of population willing to abolish DST as per the 2018 public consultation $C$. The inset shows the distribution of shares scaled by the interquartile range to identify and quantify the outliers Austria, Germany and Luxembourg, not shown in the main picture and excluded from the regression (see section 2). The low quartile was $Q_1 = 0.152\,\%$ and the high quartile, $Q_3 = 0.333\,\%$. The solid line shows the point estimates of the prediction; the dashed lines bound the 95 % prediction interval. The regression is statistically significant ($p = 0.015$) at the standard level of significance ($\alpha = 0.05$), see Table S4 in the Supplemental Information. Notice that the span of the predictor is larger than one hour: the standard unit of social time and the size of the stroke brought by DST of clocks. Horizontal bars highlight population weighted low and high $F(\phi)$ quartiles (France and Spain show the span of the European areas only). Labels show iso-3166 alpha-2 codes. **B**. The same picture but for the shares of population willing to keep regulations as per the 2018 public consultation. The association does not bring statistically significant correlations, see Table S4 in Supplemental Information. For the shares $K$ $Q_1 = 0.025\,\%$ and $Q_3 = 0.116\,\%$. In increasing values of latitude: CY Cyprus; MT Malta; GR Greece; PT Portugal; ES Spain; BG Bulgaria; IT Italy; HR Croatia; RO Romania; SI Slovenia; HU Hungary; FR France; AT Austria; SK Slovakia; LU Luxembourg; CZ Czech Republic; BE Belgium; DE Germany; PL Poland; GB United Kingdom; NL Netherlands; IE Ireland; LT Lithuania; DK Denmark; LV Latvia; SE Sweden; EE Estonia; FI Finland.

Figure 2 Scatter plots of the shares of population willing to abolish DST as per the 2018 European Commission public consultation (outcome) vs four predictors related to human activity as per HETUS. The left column shows morning time marks: sleep and other personal care offset (top) and work onset (bottom). The right column shows noon time marks: sleep and other personal cares midpoint (top), work midpoint (bottom). Time marks are given as a distance to the winter sunrise. Circles refer to round 2 (year 2010) of HETUS, and squares to round 1 (year 2000). The null hypothesis "the predictor does not explain the outcome" does not sustain at the standard level of significance for every test, see Table S5 in Supplemental Information. Solid line shows the results of the linear regression; dashed lines bound the 95 % prediction interval of the regression. Table S1 lists the data values that generated this plot. Horizontal bars highlight population weighted low and high quartiles (France and Spain show the span of the European areas only).

[univariate] descriptive statistics are presented in the report."(for Mobility and Transport, 2019, Section 3) The final reports also highlights that "even with the caveats in terms of biases and non-representation, the results can be analysed by taking into account an important differentiating factor between the Member States, namely their location and their exposure to more or less light [driven by the latitude]." Indeed the Appendix A3 in the final report considered three latitudinal clusters: above the 53rd parallel (7 Member States), below the 46th parallel (9) and the intermediate range (12). However latitude is only employed to report in Figure 28 (Appendix A.4.2, page 35) the shares of respondents to Question 2 with Member States ordered by decreasing latitude of the capital city.[1]

Our study addresses specifically these challenges and refines the statistical analysis. We test the shares of population —not the shares of respondents— the most sensitive metric in a natural experiment. Aside from the evident bulk differences in the shares of respondents and in the shares of population against and pro the current regulations that drew the attention in 2018, Figure 1 and Table S4 show that the shares of population against $C$ and pro $K$ the current regulations found different stimuli to show up at the public consultation. While the keep choice finds no relevant correlation with any metric, in line with the uncontrolled factors that impacted the pub-

---

[1] The "shares of respondents to Question 2", reported by the European Commission, should not be confused with the "shares of population to Question 2".

lic consultation, the abolish choice finds statistically significant correlations with the latitude ($p = 0.045$), with the winter sunrise time ($p = 0.01$), and with the distance of the starting point of human activity to the winter sunrise ($p = 2 \times 10^{-5}$). One kind of stimuli brought larger shares of population willing to cancel the regulations with increasing latitude, with delayed winter sunrise time and with larger shares of early risers (those who start their activity before the winter sunrise time). This stimulus was able to overplay the myriad of confounding factors that might have also impacted the distribution of shares. We note the bare meaning of $p = 2 \times 10^{-5}$: if the distribution of shares $C$ is shuffled —simulating strong uncontrolled confounding factors only— and the shuffled distribution is tested against the predictor, there are 2 odds in 100 000 tests of obtaining a greater correlation. It is very unlikely that the correlations in figure 2 arose by chance. In obtaining this result the large sample size per Member State of the shares $C$ (median value $\sim 0.33\%$ of the country population) must have played a significant role: it was able to retain significant unbiased information of the underlying population even in an uncontrolled, natural experiment.

We suggest that this primordial stimulus is linked to the primordial rationale of the clock regulations(Harrison, 2013; Hudson, 1898; Pollack, 1981; Willet, 1907) and it is associated with human physiology.(Martín-Olalla, 2019a,b, 2020) The early risers find challenging dark conditions in the winter morning. They may find challenging dark conditions after DST spring forward shift, depending on the transition date. Finally, they also find challenging bright conditions during the summer evening, which jeopardizes their bedtimes. We must note that this interplay is irrespective of latitude because everywhere the winter sunrise time and the summer sunset time are separated by twelve hours (eleven "clock" hours if DST applies). Increasing latitude simply promotes larger shares of early risers as a result of increasingly delayed winter sunrise times. On the contrary, the late risers —those persons with start times in line with the winter sunrise— seldom find these issues and show little discomfort with the practice. This group of population did not find the stimulus to show up at the consultation.

The impact of the myriad of confounding, uncontrolled factors in the distribution of shares by Member State is noted in the unbiased standard error (SE) of the fit, listed in Table S4 and Table S5 as a percentage of the sample average value of the outcome, and in the spread of the values of $C$ and $K$ shown in Figure 1. Furthermore, it is not obvious how the confounding factors can yield different preferences with clock regulations because they impact one and every aspect of social life. As an example, the Commission rightfully notes that the public consultation only targeted people with access to the Internet, and skills to respond web-based forms. It is uncertain how people can develop a strong gradient of preferences based on the access to the internet. In other words, the outcome —preferences for clock regulations— and the predictor —access to the internet— are not directly linked. The indirect impact of the predictor on the outcome must be weak once the size of the experiment is large enough.

A big, unavoidable limitation of our study is the coarse disaggregation by Member State. This issue questions whether the reported mean shares $C$ of a given Member State would sustain for every region of the Member State or, else, if a distribution of shares $C$ by smaller statistical units might have been observed. The Commission attributed little significance to this issue because the respondents were not even asked for region. In the final report, this issue is indirectly addressed when the differences in the exposure to more or less light —driven by the latitude— are noted as important differentiating factors. The sentence is meant at the level of Member States because conditions in Southern States are widely different from conditions in Northern States. However this range of exposure to more or less light is less significant at a finer level in every Member State except perhaps in Great Britain, Sweden and Finland, where differences between their Southern regions and their High North regions are still significant due to the divergence of $F(\phi)$ at their range of latitudes. We note in Figure 1 and Figure 2 interquartile ranges of the predictor at State level, see the horizontal bars. In the end, the analysis by Member State does not discard our results. On the contrary, our results urge to analyze the relationship between clock regulations and latitude at a finer level of disaggregation.

A counterexample of confounding factor with relevant impact in the distribution of shares is shown by the shares of Austria, Germany and Luxembourg where a clear, distinct, unidentified, strong confounding factor brought larger shares of population to show up at the public consultation. As a plausible hypothesis we put forward the following argument. In order to show up at the public consultation the general population first needed to know about it from public advertisement launched by the European Commission and, above all, from the impact of the consultation in mass media. We note that Austria and Germany are the two only member states where the German language is the official language; while in Luxembourg, the German language is spoken by significant shares for the population. It might have been the case that German language media put more attention on the public consultation than elsewhere. Larger shares of audiences brought larger shares of respondents compared with other Member States. We stress that the removal of these outliers in no way undermines the choice of these persons. The removal of outliers just allows to unveil correlations in the remaining dataset.

## 2. DISCUSSION

Our results show evidence that the preferences for DST regulations are impacted by environmental factors like latitude ($p = 0.045$), winter sunrise time ($p = 0.01$) and by societal metrics like the distance of start times to the winter sunrise ($p = 2 \times 10^{-5}$).

The findings are counter the prevailing view described by position statements issued by medical associations(Malow, 2023; Rishi *et al.*, 2024; Roenneberg *et al.*, 2019b). It is showing that in order to build up shares of population against the "annoying" DST regulations, shares of early risers must be built up as well. They would face "annoying" dark mornings. The circadian golden standard of year-round pre-set schedules with start times aligned with the winter sunrise seems to be unstable in some societies. Indeed, this golden standard must have been present at the beginning of the 20th century, and it was soon deprecated in United Kingdom, urban areas of United States, Ireland and Portugal, by giving birth to the biannual changing of the clocks. Eventually, by advancing clocks in spring and delaying it back in autumn, these societies prevented the growing use of artificial light from incorporating more human activity into the dark winter morning(Martín-Olalla, 2022). As a result, the biannual clock change kept the number or early risers at bay; the shares of population against the regulations did not grow either; and the regulations probed stable.

Our results also challenge the frequent argument that the seasonal clock regulations bring a circadian misalignment during the DST period because the social clock is "artificially" out of sync with the sun clock(Johnson and Malow, 2022). This claim is supported by research studies that associate position in a time zone with hazards(Gentry *et al.*, 2022; Giuntella and Mazzonna, 2019). If DST brought a circadian misalignment due to the misalignment between the social clock and the sun clock, then the shares of population against DST in the public consultation and the latitude should not correlate, because the misalignment does not depend on the latitude.

The misunderstanding arises because the misalignment is associated with clock time and with mean solar time (noon). However, human preferences and practical decisions are connected with sunrise, and therefore with latitude and seasons(Martín-Olalla, 2018). As long as the clock regulations do not bring the starting points ahead of the sunrise, and the bedtimes ahead of the sunset, the alleged misalignment is irrelevant for practical decisions and, very likely, a matter of personal preferences.[2]

Our results may also help to understand why many polls display larger preferences for permanent DST, a choice that bothers the circadian community(Antle *et al.*, 2022; Coogan *et al.*, 2022). More than expressing a science-informed preference for this setting, the polls might just be expressing that newer generations still love their current summer earlier start times that allow a better harvesting of their leisure time. They do not see late start times and late end time during the summer season.

Because the shares of population pro DST did not show up consistently in the 2018 public consultation, our methodology cannot assess whether above some circle of latitude the majority is against the current regulations. Nonetheless, the findings of this manuscript, supported by such large sample size, have a substantial impact in the current wave of discussion around summertime arrangements and, specifically, challenges the one-size-fits-all solutions that usually show up. As an example, we put forward the past preference of the European Commission: either every Member State must practice summertime arrangements (the *statu quo* now implemented through Directive 2000/48/EC) or they all must abandon the practice.

In sharp contrast, our methodology did find a significant stratification of preferences with latitude and with human activity. Therefore we understand that a science evidence-based policy should allow Member States to opt-out from the current setting, and should implement binding transition dates only for those Member States who wanted to continue the seasonal practice. Chile and Australia align with this choice and clock regulations stratify with latitude in these countries.

Compared to the European Union, the contiguous USA happen to experience more similar seasonal cycles of light and dark, with perhaps the exception of Florida, close to the Tropic of Cancer. We do not know of a public consultation in USA similar to the public consultation launched by the European Commission. Yet, the US starting point of human activity is in line with the winter sunrise(Martín-Olalla, 2018), as observed in United Kingdom or Italy. Therefore we would expect the US general population would not strongly oppose seasonal DST in self-reported surveys. This would also be in line with the long standing record of the practice (some one hundred years in the US urban areas). On the contrary, the Russian starting point of human activity is in line with the Scandinavian and Baltic starting points as deduced from reported values of school starting times(Borisenkov *et al.*, 2017). As a result, year-round DST failed to sustain in Russia after 2015, when year-round ST was adopted. While this choice was celebrated by the circadian community we bring the attention to the fact that this is a consequence of having previously advanced the starting point of human activity, due to the challenging conditions associated with the Russian winter photoperiod, and may not necessarily apply elsewhere.

The bi-annual change of the clocks is abrupt, annoying and hazardous, but societies seldom practice them for the

---

[2] Eventually, beyond the Polar Circle and during the Polar night or during the midnight sun period, few can be said about the alignment of the human activity in terms of clock time.

fun of it, or only for economic reasons. They happen to manifest a simple, physiological adaptation to seasons once pre-set schedules were established, and when the environment demands it, within a range of intermediate latitudes where $F(\phi)$ ranges from 1 h and 2 h (30° to 50° in latitude) so that DST effectively binds the starting point of human activity to the sunrise (see the annotated box in Supplemental Information, Figure S2).

## 3. METHODS

### 3.1. Daylight Saving Time and geography

DST transitions are often associated to the longitude $\lambda$ and the time zone offset $Z$ (usually a whole number of hours).(Giuntella and Mazzonna, 2019; Johnson and Malow, 2022; Roenneberg *et al.*, 2019a) After all, time zone designation is the modern way by which we express the reference of time and clocks move from wintertime (standard time) to summertime (DST).

However, the longitude and the time zone offset only set the difference between solar ephemerides (solar time) and clock time. Specifically the (local) time offset $Z - \lambda/\Omega$ is the time difference between solar noon and clocktime midday. Here $\Omega = 15\,°\,\mathrm{h}^{-1} = 0.262\,\mathrm{rad\,h}^{-1}$ is Earth's angular rotation speed. With solar noon occurring every 24 h day after day, irrespective of season, and clocktime midday occurring every 24 h —we assume no clock regulations here— time offset plays no leading role in the seasonal regulations of clocks.

The human response to, and the human preferences for, these arrangements must depend chiefly on the latitude $\phi$ because this is the one and only factor that sets the seasonal variability of sunrise times through the seasonal factor:

$$F(\phi) = \frac{\pi/2 - \cos^{-1}(-\tan\phi\tan\varepsilon)}{\Omega}, \qquad (1)$$

where $\varepsilon = 23.5°$ is Earth's axial tilt. Figure S2 in the Supplemental Information shows a scatter plot of $F(\phi)$.

The seasonal $F(\phi)$ is a time magnitude that carries information for the sunrise and sunset times and their spread. The factor is defined so that the winter sunrise time is $6\,\mathrm{h} + F(\phi)$; while the summer sunrise time is $6\,\mathrm{h} - F(\phi)$; and $2F(\phi)$ is the spread of sunrise times in a year. Likewise sunset times go as $18\,\mathrm{h} \mp F(\phi)$; and the photoperiod, as $12\,\mathrm{h} \mp 2F(\phi)$(Martín-Olalla, 2018). Therefore, save for an unimportant constant value, testing $F(\phi)$ is testing any relevant parameter associated with light conditions like the winter sunrise time is. It must be noted that all times here are mean solar times. Clock time values are obtained by adding the local time offset.

With $F(\phi)$ a small and slow varying function at low latitudes (see Figure S2 in Supplemental Information)

the stroke of one hour the clock regulations set finds little support in the Tropic. Likewise with $F(\phi)$ high and steepest it would find little support in the Polar region, because the varying seasons brings a span of sunrise time much larger than one hour. At intermediate latitudes the stroke is balanced with better alignment of starting times with sunrise time, smaller exposition to the damaging central hours of the day during the summer season and with an improvement on the leisure time during this season(Martín-Olalla, 2019a).

Little is known on how latitude impacts the public preferences for the practice, save for the obvious fact that the practice is seldom used at the Tropics. The European Union is an adequate environment to test this idea because the supranational ensemble extends from 35° (Cyprus) to the Polar Circle (Finland and Sweden), which sets vividly different seasonal cycles of light and dark: sunrise time can span as few as less than three hours (Cyprus) to more than seven hours (Finland).

Table S1 in the Supplemental Information lists European Union Member States and United Kingdom in increasing values of latitude, with time offset and the seasonal factor. Figure S3 in Supplemental Information shows an Albers projection of Europe and visualizes longitude and latitude.

Geographical data were retrieved from the GeoNames database. We searched for populated places with more than 500 inhabitants. Population weighted low quartile, median and high quartiles for the distribution of latitude and longitude were determined. We also determined the distribution of winter sunrise times per country and their population weighted quartiles.

### 3.2. The 2018 public consultation on summertime arrangements

From 4 July 2018 to 16 August 2018 the European Commission launched a web-based public consultation on summertime arrangements in their *Have your say* portal. The final report counts $N = 4\,540\,554$ million replies to the consultation from citizens in the then 28 Member States(for Mobility and Transport, 2019). A clear majority, 84 % of respondents, demanded the cancel of DST. A fortnight after the consultation ended, the Juncker Commission launched the proposal to cancel of DST. However Member States could not agree on which time should survive, a most complicated decision to which the consultation gave no clear preference: 56 % of respondents preferred summer time, 32 %, winter time.

Public consultations are not surveys due to the lack of sample extraction design. The European Commission acknowledges that the consultation on time arrangements had "a self-selection bias of the respondents towards the views of those who choose to respond to the consulta-

tion"[3]. Unlike polls, where respondents are urged to answer a question, the public consultation was a self-reported survey where some people choose to respond the consultation.

In our methodology, we analyzed the two choices to question 2 separately. We do not test those against DST versus those pro DST. We do not test the net balance of those against and pro DST. We test those against DST irrespective of how many individuals showed up in the public consultation pro DST. And we test those pro DST irrespective of how many individuals showed up in the public consultation against DST. Either group of population is isolated.

We took the data from Table 8 (Appendix B.1.2, page 41) in the final report, which lists the absolute numbers of answers by citizens to Question 2 in the consultation: *to keep or abolish the current arrangement?* We also retrieved the population numbers $P$ for 2018 by Member State from the Eurostat database (`demo_pjanind.tsv`). By scaling with the population numbers we produced the *shares of population* against the current arrangement $C$ by Member State and the *shares of population* in favor of the current regulations $K$, as per the public consultation. We note that our metric was not reported by the European Commission, who instead reported the *shares of answers* or *shares of respondents* against and in favor of the current regulation in Figure 9 (page 14, Member States ordered in decreasing values of shares against) and in Figure 28 (page 35, Member States ordered in decreasing values of latitude). The Commission only reported the participation rate by Member State: number of respondents divided by population, see Table 2 (pages 8 and 9). A posterior analysis of the shares of population allows to identify which stimuli prompted the population to take the consultation, see section 1 and section 2.

The quartiles of the distributions of shares were: $Q_1 = 0.152\%$, $Q_2 = 0.327\%$, $Q_3 = 0.491\%$ (against), and $Q_1 = 0.025\%$, $Q_2 = 0.057\%$, $Q_3 = 0.116\%$ (keeping). The interquartile range was IQR $= Q_3 - Q_1 = 0.339\%$ (against) and IQR $= 0.090\%$ (keeping). While these sizes are small relative to the total population of a country, we note that they are much larger than the sample size of a standard poll or survey.

We computed the distance to the third quartile in units of the IQR. Austria, Germany and Luxembourg showed distances larger than 1.5 in either distribution; Cyprus

got a distance larger than 1.5 in the keeping distribution. We note that 1.5 is a common threshold for outlier identification in descriptive statistics. Furthermore these distances were higher or close to 3, a common threshold for *hard* outliers. These outliers were removed from the bivariate analyses, see Section 1.3 for the implications.

We emphasize that the replies to the target question express a feedback to the current *statu quo*, under which most of the respondents have been living during long time. We do not analyze the preferences for which clock should survive (Question 3). Replies to this question express, for the majority of the population, preferences for hypothetical, unknown scenarios. These personal preferences may or may not sustain in time if they materialize.

Table S2 lists the population numbers and the replies to question 2 in the Member States that took part in the consultation, and the distance of the outliers to the third quartile.

### 3.3. Harmonized European Time Use Survey

In addition to the geographical variables, the outcome was tested against the phase of human cycles. For this purpose we retrieved the daily rhythms available at HETUS(Eurostat, 2010), a collection of large scale time use surveys which were carried out in two rounds (2000 and 2010). Of the 25 Member States with meaningful $C$, 17 of them have reported time use statistics to Eurostat and will be tested here.

We focus on the two activities of interest in connection to the seasonal regulations of time: sleep and other personal care (code `ACOA`) and work as a primary and secondary activity, including the transfer from home to work, (code `AC1_2_TR`). The first activity largely reproduces the sleep/wake cycle in the participant state, with a minor contribution of other personal care (washing, clothing and the like). The second activity refers to the labor cycle. Both activities are linked one way or the other to the cycle of light and dark, with which the time regulations are associated.

HETUS reports the participation rate in an activity by the local time of the day in 144 distinct, 10-minute time slots. The sum of all participation rates is the fraction of time spent in the activity. An assessment of the phase of the daily rhythm is provided by the midpoint (centroid) of the activity, see Figure S4a in Supplemental Information: the time slot when half the daily time spent has been consumed and half remains. For this purpose the daily rhythm is started when the participation rate is minimal: 4am (work) and 7pm (sleep and other personal cares).

We also assessed the starting point of work (or work onset) and the end point of the sleep and other personal cares (or sleep offset) by scaling the daily rhythm with the daily maximum participation rate and retrieving the

---

[3] In "Public Consultation On EU Summertime Arrangements Report of Results" a working document by the Commission Staff accompanying the document "Proposal for a Directive of the European Parliament and of the Council discontinuing seasonal changes of time and repealing Directive 2000/84/EC", document number 52018SC0406, https://eur-lex.europa.eu/legal-content/EN/TXT/?uri=CELEX%3A52018SC0406

time slot when the scaled participation rate is larger than one half (work), or smaller than one half (sleep). See figure S4b in Supplemental Information.

For the purpose of comparison we converted the local time marks into mean solar timemarks by removing the local time offset, see Table S1. We also computed the distance to the winter sunrise, removing further the seasonal factor $F(\phi)$. The distance to the winter sunrise is specifically associated with ambient-light conditions and with seasons, since it reports the conditions in the most challenging day of the year: that with the latest sunrise time and shortest photoperiod. We have previously shown that the winter sunrise time is a synchronizer for the human activity after analyzing time use surveys(Martín-Olalla, 2018, 2019c)

In addition to the concerns and limitations that the study design of the public consulation presents for our analysis we also mention a further limitation. The two activities here analyzed refer to distinct population structures. The work activity is filled only by the fraction of survey respondents that do work, while the sleep and other cares activity is filled by every individual taken part in the survey. In contrast, it is not possible to extract the responses given by employees only in the 2018 public consultation.

## 4. DATA AVAILABILITY

Results from the public consultation are publicly available in tabular format(for Mobility and Transport, 2019). We only made use of the column "Abolishing the switching for all EU-MS Citizens" in Table 8, Section B.1.2, page 41. We discarded the 8758 replies not assigned to any Member State.

HETUS data are publicly available at Eurostat(Eurostat, 2010) for all Member States that participated in the survey except Sweden. We took Sweden results from an earlier study(Martín-Olalla, 2018). In the HETUS database we took the participation rate in the main activity (wide groups) by sex and time of the day, file `tus_00startime`.

European population numbers for 2018 were extracted from Eurostat's Demography, population stock and balance database: population (national level), population on 1 January by age and sex, file `demo_pjan`.

Geographical coordinates (latitude, longitude, time zone offset) were extracted from `GeoNames` database (https://www.geonames.org/). We retrieved the file `cities500.zip`, and produced population quartile values of latitude, longitude and winter sunrise time for every country in the public consultation. We exclude population places below 500 inhabitants and places flagged with the PPLX feature code (section of populated place). The datafile was downloaded on 22 April 2024.

## ACKNOWLEDGMENTS

Along this manuscript United Kingdom is listed as a EU Member State since it participated as such in the public consultation of 2018 and in HETUS rounds. United Kingdom ceased to be a EU Member State on February 1, 2020. Removing the British results from the field does not alter the findings of our study in a substantial way.

All authors contributed equally to this work.

Table S2 The results to question 2 in the 2018 public consultation launched by the European Commission. Member States are listed in increasing values of latitude. Each answer to the question is given in absolute numbers and in shares of the country population. The quartiles of the distributions of shares are: $Q_1 = 0.152\%$, $Q_2 = 0.327\%$, $Q_3 = 0.491\%$ (against), and $Q_1 = 0.025\%$, $Q_2 = 0.057\%$, $Q_3 = 0.116\%$ (keeping). The distance to the third quartile in units of the interquartile distance $(Q_3 - Q_1)$ is shown in parenthesis when this metric is larger than 1.5, a common criterion for outlier identification.

Table S3 The time marks associated with the sleep and other personal cares and the work cycles as per HETUS. Countries are listed in increasing values of latitude. The third left-most column list the round of HETUS: round 1 was taken around 2000; round 2 around 2010. Round 3 is currently in progress. Figure S4 shows the methodology to asses midpoints and offset/onset time marks.

| | Outcome | Pearson-$R^2$ | $p-$val | Slope [95 % CI] | Unbiased SE | Outliers |
|---|---|---|---|---|---|---|
| *Non-seasonal predictors* | | | | | | |
| Longitude, $\lambda$ | Absolish $C$ | 0.075 | 0.185 | | 71 % | AT DE LU |
| | Keep $K$ | 0.061 | 0.245 | | 80 % | AT CY DE LU |
| Time offset, $Z - \lambda/\Omega$ | Absolish $C$ | 0.008 | 0.675 | | 74 % | AT DE LU |
| | Keep $K$ | 0.000 | 0.927 | | 83 % | AT CY DE LU |
| *Seasonal predictors* | | | | | | |
| Latitude, $\phi$ | Absolish $C$ | 0.166 | 0.043 | 0.013[0.000, 0.026] | 68 % | AT DE LU |
| | Keep $K$ | 0.027 | 0.442 | | 82 % | AT CY DE LU |
| Winter sunrise time, $6\,\text{h} + F(\phi)$ | Absolish $C$ | 0.231 | 0.015 | 0.182[0.039, 0.326] | 65 % | AT DE LU |
| | Keep $K$ | 0.009 | 0.659 | | 82 % | AT CY DE LU |

Table S4 The association between the geographical data (predictors) and the shares of population willing to abolish $C$ or willing to keep $K$ the current time arrangements as per the 2018 public consultation launched by the European Commission (outcome). The null hypothesis fails to sustain for seasonal predictors and the abolish choice (see Figure 1 in the main text) and sustains for non-seasonal predictors (see Figure S1 in the Supplemental Information) and for the keep choice (see Figure 1). The unbiased standard error (SE) is scaled by the sample average value of the either outcome (0.325 %, against, and 0.058 %, keeping). The null hypothesis of normally distributed residuals sustained in every regression at the standard level of significance. The slopes are given in basis points per degree (latitude) and basis points per hour (seasonal factor). The positive value shows larger shares of population willing to abolish the current time regulations with higher latitude and higher seasonal variability. The sample size was 960 199 replies to the public consultation from 25 member states for the abolish choice, and 174 489 replies from 24 member states for the keep choice.

| Predictor | Pearson-$R^2$ | $p-$val | Slope[95 % CI] | Unbiased SE |
|---|---|---|---|---|
| Sleep and other personal cares offset | | | | |
| Time distance to solar noon | 0.001 | 0.897 | | 84 % |
| Time distance to winter sunrise | 0.472 | 0.002 | $-0.31[-0.49, -0.13]$ | 61 % |
| Work onset | | | | |
| Time distance to solar noon | 0.128 | 0.159 | | 79 % |
| Time distance to winter sunrise | 0.707 | $< 0.001$ | $-0.36[-0.49, -0.24]$ | 46 % |
| Sleep and other personal cares midpoint | | | | |
| Time distance to solar noon | 0.021 | 0.578 | | 83 % |
| Time distance to winter sunrise | 0.406 | 0.006 | $-0.25[-0.41, -0.08]$ | 65 % |
| Work midpoint | | | | |
| Time distance to solar noon | 0.001 | 0.910 | | 84 % |
| Time distance to winter sunrise | 0.543 | $< 0.001$ | $-0.36[-0.54, -0.18]$ | 57 % |
| Geographical predictors | | | | |
| Longitude, $\lambda$ | 0.060 | 0.345 | | 82 % |
| Time offset, $Z - \lambda/\Omega$ | 0.000 | 0.970 | | 84 % |
| Latitude, $\phi$ | 0.364 | 0.010 | $0.02[0.01, 0.04]$ | 67 % |
| Winter sunrise time, $6\,\mathrm{h} + F(\phi)$ | 0.439 | 0.004 | $0.28[0.11, 0.45]$ | 63 % |

Table S5 The association between time marks of human activity —measured through two distinct metrics— (predictor, see Table S3) and the shares of population willing to cancel the time regulations as per the 2018 public consultation (outcome, see Table S2) in $N = 17$ Member States that reported Hetus statistics. Blue ink annotates $p-$values below the standard level of significance ($\alpha = 0.05$), which occurs only when predictors are measured relative to the winter sunrise. The negative slope shows that shares against the current regulations increases with earlier starting points relative to winter sunrise time. Slopes are given in basis points per hour. The unbiased standard error of the fit is scaled by sample average value of the fitted shares $C$ (0.326 %) and the result expressed as a percentage. The null hypothesis of normally distributed residuals sustains in every regression at the standard level of significance. For comparison the association with geographical predictions in this subset is also shown.

**Appendix B: Additional figures**

The section is intended to be included in a dedicated Supplemental Information file if the manuscript is published. It can be tailored to comply with the journal's Guidelines.

Figure S1 The association between the time offset —difference between noon and midday— and the shares of population willing to cancel the regulations as per the 2018 public consultation $C$. Germany (3.18 %), Austria (2.27 %) and Luxembourg (1.38 %) are not shown in the picture. The solid line shows the point estimates of the prediction; the dashed lines bound the 95 % prediction interval. The null hypothesis "shares $C$ do not depend on time offset" sustains ($p = 0.696$ at the standard level of significance ($\alpha = 0.05$), see Table S4 in the Supplemental Information. Labels show iso-3166 alpha-2 codes, see table S1.

Figure S2 The evolution of the seasonal factor $F$ as a function of latitude $\phi$. The seasonal factor is defined in Eq. (1) so that it equals to zero at the Equator. The seasonal factor gives the advance or delay of the sunrise and sunset times at the solstices relative to the Equatorial standard. The right axis shows the corresponding winter photoperiod (and the summer scotoperiod) $12\,\mathrm{h} - 2F(\phi)$. Data points annotate the Member States. The seasonal factor was modeled for a point-sized Sun and a refractionless atmosphere. The box expands from $30°$ to $50°$ and yields $F(\phi)$ from $1\,\mathrm{h}$ to $2\,\mathrm{h}$. It is an educated guess for the utility range of seasonal regulations of time.

Figure S3  An Albers projection of Europe with the countries participating in the 2018 European Commission public consultation on summertime arrangements (in shade and labeled). Dashed meridians annotate time meridians. Solid meridians annotate the bounduaries of the physical time zones. Circles of latitudes annotate straight values of $F(\phi)$, starting at $F = 1.5\,\mathrm{h}$ (southern most) and ending at $3.5\,\mathrm{h}$ (northern most) in steps of $0.5\,\mathrm{h}$. Color shades highlight time zones; from west to east, Western European Time ($Z = 0$), Central European Time ($Z = 1\,\mathrm{h}$) and Eastern European Time ($Z = 2\,\mathrm{h}$). Vertical bar annotates the quartile range of population weighted latitude at the median population weighted latitude. The black horizontal bar locates the pupulation median latitude and longitude for the country, listed in Table S1. The map was made with Natural Earth, a free vector and raster map data available at https://www.naturalearthdata.com/.

Figure S4 Determination of the midpoint and work onset. On the left panel the daily rhythm of labor as per HETUS. The area enclosed by the daily rhythm scales with the daily average total work. The shaded areas break even the total area. The hour of the day when this happens is the *midpoint* of the labor cycle. On the right panel, the maximum participation rate is halved. Work onset is determined as the hour of the day when the participation rate first exceeds the maximum daily participation rate. Similar analysis allow to assess the midpoint of the sleep/wake cycle and the sleep offset.
