Abstract

Background: Recent randomized controlled trials have demonstrated similar outcomes in terms of ischemic stroke incidence after carotid endarterectomy (CEA) or carotid artery stenting (CAS) in asymptomatic carotid disease, while CEA seems to be the first option for symptomatic carotid disease. The aim of this meta-analysis is to assess incidence of silent cerebral microembolization detected by Magnetic Resonance Imaging (MRI) following these procedures.

Methods: A systematic search was conducted using PubMed, Scopus and Cochrane databases including comparative studies involving symptomatic or asymptomatic patients undergoing either CEA or CAS, and reporting on new cerebral ischemic lesions in post-operative MRI. The primary outcome was the newly detected cerebral ischemic lesions. Pooled effect estimates for all outcomes were calculated using the random-effects model. Pre-specified random effects meta-regression and subgroup analysis were conducted to examine the impact of moderator variables on the presence of new cerebral ischemic lesions.

Results: 25 studies reporting on total 1827 CEA and 1500 CAS interventions fulfilled the eligibility criteria. The incidence of new cerebral ischemic lesions was significantly lower after CEA comparing to CAS, regardless of the time of MRI assessment (first 24 hours; OR: 0.33, 95% CI: 0.17-0.64, $p < 0.001$), (the first 72 hours, OR: 0.25, 95% CI 0.18-0.36, $p < 0.001$), (generally within a week after the operation; OR: 0.24, 95% CI: 0.17-0.34, $p < 0.001$). Also, the rate of stroke (OR: 0.38, 95% CI: 0.23-0.63, $p < 0.001$) and the presence of contralateral new cerebral ischemic lesions (OR: 0.16, 95% CI 0.08-0.32, $p < 0.001$) were less frequent after CEA. Subgroup analysis based on the study design and the use of embolic protection device during CAS showed consistently lower rates of new lesions after CEA.

Conclusions: CEA demonstrates significant lower rates of new silent cerebral microembolization, as detected by MRI in postoperative period, compared to CAS.

Introduction

Both carotid endarterectomy (CEA) and carotid artery stenting (CAS) reduce the risk of stroke or transient ischemic attack (TIA) with relatively low morbidity and mortality in people with specific comorbidities and features, as well as suitable carotid lesions¹⁻⁴. One of the main risks during these procedures is embolization. CEA is the preferred treatment for both symptomatic and asymptomatic individuals; nonetheless, in high-risk patients CAS is an alternative therapeutic option⁵. Despite its less invasive nature, CAS seems to have higher risk of periprocedural embolization compared to CEA most likely due to manipulation of endovascular devices in the aortic arch or in friable plaques⁶⁻⁸.

While stroke/TIA after carotid revascularization is comparatively rare, subclinical microembolization was found to occur more frequently⁹⁻¹¹. Silent microembolization episodes may nowadays be recognized more easily than in the past, with transcranial Doppler and diffusion weighted Magnetic Resonance Imaging (DWI-MRI) providing the highest diagnostic accuracy^{5,12}. DWI-MRI is a high-sensitivity imaging tool capable of detecting silent infarcts following carotid revascularization and providing important information on the safety of various procedures.

Various studies reported the occurrence of confirmed DWI-MRI silent microembolization following CEA or CAS¹³⁻¹⁵. To synthesize the most recent data from the current literature on the incidence of silent cerebral microembolization following CEA and CAS, we carried out a systematic review and meta-analysis of studies that used DWI-MRI for microembolization detection before and after carotid revascularization. Our research attempts through rigorous mathematical methodology to provide concrete evidence and compare the most updated incidence of silent post-operative microembolization between CEA and CAS.

Material and Methods

Study design and inclusion/exclusion criteria

This systematic review and meta-analysis were performed according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-analyses) guidelines¹⁶ and were prospectively registered in the International Prospective Register of Systematic Review (PROSPERO) database (registration number: CRD42023494604). We applied the PICO (Population/Participants, Intervention, Comparison, and Outcome) criteria to define our research question:

1. Population/Participants: Adult patients, symptomatic or asymptomatic, with carotid stenosis undergoing operation and performing pre and post-procedural MRI.
2. Intervention: CEA
3. Comparison group: CAS
4. Outcomes: The primary assessed outcome was the new cerebral ischemic lesions shown in the post-procedural MRI. The secondary outcomes were the presence of contralateral cerebral ischemic lesions and stroke.

We also performed subgroup analyses according to the time of postoperative MRI, the study design, and the use of embolic protection device with the CAS technique. Pre-specified random effects meta-regression analysis was conducted to examine the impact of pre-operative symptoms, hypertension, smoking status and diabetes on the presence of new cerebral ischemic lesions. Stroke was defined as either ipsilateral or contralateral, cortical or vertebrobasilar, ischemic or hemorrhagic strokes, during the first 30 postoperative days.

Original clinical studies, including both randomized trials and non-randomized prospective/retrospective comparative studies, reporting on the outcomes of interest in patients undergoing CEA and CAS, were deemed eligible for inclusion. The exclusion criteria for the present systematic review were defined as follows: (i) irrelevant articles, (ii) non-comparative studies (<2 study arms), (iii) studies not directly comparing CEA and CAS for the outcomes of interest, (iv) animal and in-vitro studies, (v) case reports, (vi) narrative or systematic reviews and

meta-analyses, letters to the editor and comments, (vii) non- English language articles and (viii) published abstracts with no published full text. Ultimately the studies identified were assessed for overlap. In cases where multiple studies reported on the same population, only the larger study or the one with the best quality of data was included in the present meta-analysis.

Literature search strategy

Eligible studies were identified by searching through the MEDLINE (via PubMed), Scopus, and Cochrane Library databases (last search: November^{29th}, 2023) using the algorithm: (CEA OR (endarterectomy, carotid[MeSH Terms])) OR endarterectom*) AND ((stent[MeSH Terms]) OR CAS OR ("carotid stent") OR ("carotid stenting") OR (angiopl*)) AND ("diffusion weighted imaging" OR DWI OR MRI OR ("magnetic resonance imaging") OR ("ischemic lesion") OR (diffusion magnetic resonance imaging[MeSH Terms])) AND ((arterial disease, carotid[MeSH Terms]) OR (carotid arteries[MeSH Terms]) OR (caroti*) OR (carotid stenosis[MeSH Terms]) OR (carotid stenoses) OR (arterial disease, carotid[MeSH Terms]) OR "carotid surgery"). No search filters were applied to our search. Title and abstract screening and full-text eligibility were assessed by two independent investigators. Any disagreement was resolved after a discussion with a third reviewer. We also searched the reference list of the included studies for potentially eligible studies using the snowball methodology¹⁷. The Covidence reference and article manager software was used for all stages of the database search and study selection¹⁸.

Data extraction and assessment of the risk of bias

Two investigators independently extracted the data into a pre-designed standardized form. Patients' baseline characteristics as well as peri-operative data and post-operative outcomes of interest were collected. All the outcomes of interest occurred in the first 30 days after the operation. The Risk of Bias in Non-Randomized Studies of Interventions tool (ROBINS-I) and the revised

Cochrane risk of bias tool for randomized trials (RoB 2) were systematically used to assess included studies for risk of bias in non-randomized studies and in RCTs, respectively^{19,20}. The papers and their characteristics were classified into low, moderate, serious, or critical risk of bias with ROBINS-I tool and low, some concerns or high risk of bias with RoB2 tool. Two independent reviewers assessed the risk for bias. When there was disagreement, a third reviewer checked the data and made the final decision.

Statistical Analysis

Data Pooling

Continuous variables were summarized using means and standard deviations (SDs), while categorical variables were summarized by frequencies and percentages. The Hozo et al. and the Wan et al. methods were used to estimate the means and standard deviations of continuous variables whenever medians and ranges²¹ and median and interquartile ranges were provided²², respectively. Data were extracted and entered into tables and the outcomes were analyzed cumulatively.

Meta-Analysis

We calculated odds ratios (ORs) and 95% confidence intervals (CIs) for all individual studies based on the extracted data, using 2 x 2 tables for each categorical outcome. OR >1 indicated that the outcome was more frequently present in the CEA group. A treatment arm continuity correction was adopted in studies with zero cell frequencies²³. Between-study heterogeneity was assessed through Cochran Q statistic and by estimating I^2 . I^2 greater than 50% and $p < 0.1$ indicated significant heterogeneity. Due to the significant between-study clinical heterogeneity, we used the random-effects model (DerSimonian–Laird) to calculate the pooled effect estimates for all outcomes²⁴. A forest plot for each outcome was used to display the pooled

estimates graphically. Publication bias was assessed via funnel plots. Egger's test was used when at least 10 studies were included in the analysis of each outcome of interest and $p < 0.10$ was considered statistically significant, indicating possible publication bias. Subgroup analysis was performed according to the time of postoperative MRI, the study design and the use of embolic protection device with the CAS technique. Pre-specified random effects meta-regression analysis was conducted to examine the impact of moderator variables on the presence of new cerebral ischemic lesions. Specifically, using this technique we attempted to assess the effect of pre-operative symptomatic status, hypertension, smoking and diabetes on the incidence of newly detected lesions. These moderator variables were expressed as difference in rate of occurrence in the CEA versus the CAS group. Statistical analysis was performed using Stata/SE version 18 (Stata Corp, College Station, TX, USA).

Results

Study and Patient characteristics

The literature search yielded 804 potentially eligible articles after duplicates were removed, of which 66 underwent full-text evaluation. A total of 21 studies were excluded due to overlapping populations. Eight analyses of the International Carotid Stenting study (ICSS) were identified²⁵⁻³². Among these, we selected the one with the largest number of patients and reporting granular data of the outcomes of interest²⁷. We used the same methodology to conclude to the 1 study³³ and exclude the other 6 analyses reporting on patients from the Veterans Affairs Palo Alto Health Care System³⁴⁻³⁹. In 1 study we preferred to use in our analysis the data from the propensity matched pair of patients, and not from the entire original population⁴⁰. A non-English written study was also excluded from our pooled analysis because in the Spanish language the critical assessment of the study's quality may be inaccurate⁴¹. Finally, 25 studies reporting on a total of 3327 patients undergoing CEA and CAS for carotid stenosis, fulfilled the inclusion criteria and were included in

our quantitative data analysis, as summarized in the PRISMA flowchart (**Figure 1**)^{27,33,40,42–63}. Among them, a total of 3366 procedures were reported, 1861 CEA, and 1505 CAS. Pre and post-operative MRI was performed in total 1827 of 1861 CEA procedures and 1500 of 1505 CAS interventions. The baseline characteristics of the included studies, the patient's demographics, and the perioperative outcomes are summarized in **Table 1**, **Supplementary Table 1** and **Supplementary Table 2**, respectively.

Study quality and publication bias assessment

Of the 25 included studies in the final analysis, 22 were non-randomized studies^{33,40,43–56,58–63} (7 retrospective and 15 prospective) and 3 were randomized controlled trials^{27,42,57}. In 1 of the 22 non-randomized studies, the propensity score matching technique was used to adjust preoperative patients' demographic and comorbidity data⁴⁰. Seven non-randomized studies were considered with serious risk of bias: 6 due to confounding and 1 due to missing data (**Supplemental Figure 1**). The RCTs were deemed of some concerns in terms of randomization, except one that was detected with high risk of bias (**Supplemental Figure 2**). The funnel plots assessing for publication bias for the primary outcome of the presence of new ischemic cerebral lesions and the stroke rate are presented in **Supplemental Data File 1**. No publication was identified with the Egger's test and through visual assessment of the funnel plots.

Outcomes of interest

New cerebral ischemic lesions in post-operative MRI

24-hours post-procedure

In 8 studies the MRI was performed during the first 24 hours^{44–46,49,50,54,56,57}. The rate of new cerebral ischemic lesions was significantly lower in the CEA group (14.3%, 112/782)

compared to the CAS group (41.3%, 204/494) (OR: 0.33, 95% CI: 0.17-0.64, $p < 0.001$). The statistical heterogeneity was considerable ($I^2 = 78.75\%$) (**Figure 2**). The presence of contralateral new ischemic cerebral lesions was reported in 5 studies^{44,46,49,56,57}. The incidence of contralateral ischemic lesions was significantly lower in the CEA group (0.5%, 2/399) compared to CAS (8.7%, 27/310) (OR: 0.13, 95% CI 0.04-0.42, $p < 0.001$). The statistical heterogeneity was low ($I^2 = 0.00\%$) (**Supplemental Figure 7**).

72-hours post-procedure

The MRI was performed within 72 hours after the procedure in 22 studies^{27,33,40,42-51,54-57,59-63}. The incidence of new cerebral ischemic lesions was significantly lower after the CEA procedures (13.6%, 237/1738) compared to CAS (40.4%, 567/1404) (OR: 0.25, 95% CI 0.18-0.36, $p < 0.001$). The statistical heterogeneity was substantial ($I^2 = 68.74\%$) (**Figure 3**).

One week post-procedure

All 25 studies performed the MRI within a week after the operation^{27,33,40,42-63}. The rate of new cerebral ischemic lesions was significantly lower in the CEA group (13.7%, 251/1827) compared to the CAS group (41.1%, 616/1500) (OR: 0.24, 95% CI: 0.17-0.34, $p < 0.001$). The statistical heterogeneity was substantial ($I^2 = 66.85\%$) (**Figure 4**). Eleven studies reported data regarding the presence of contralateral ischemic cerebral lesions^{27,40,42,44,46,47,49,55-57,60}. The incidence of contralateral ischemic lesions remains significantly lower after the CEA procedures (1.4%, 9/649) compared to CAS technique (12.3%, 75/612) (OR: 0.16, 95% CI 0.08-0.32, $p < 0.001$). The statistical heterogeneity was low ($I^2 = 00.00\%$) (**Supplemental Figure 8**).

Stroke

The overall stroke rate was available in 17 studies including 28 stroke events after CEA (1.6%, 23/1429) and versus 53 events in the CAS group (4.7%, 53/1124)^{27,43–47,49,51,52,54–59,61,62}. The stroke rate was significantly lower in CEA group compared to CAS technique (OR: 0.38, 95% CI: 0.23-0.63, $p < 0.001$). The statistical heterogeneity was low ($I^2 = 00.00\%$) (**Figure 5**).

Subgroup analysis

Study design

The incidence of new cerebral ischemic lesions was significantly lower after CEA comparing to CAS both in RCTs or PSM (CEA 21.4%, 46/215 vs CAS 48.5%, 116/239, OR: 0.34, 95% CI:0.16-0.75, $p = 0.01$) and non-randomized studies (CEA 12.7 %, 205/1612 vs CAS 39.6%, 500/1261, OR: 0.23 95% CI:0.15-0.33, $p < 0.001$). The statistical heterogeneity remained substantial in both RCTs or PSM ($I^2 = 62.98\%$) and non-randomized studies ($I^2 = 68.55\%$) (**Supplemental Figure 9**). There was no statistically significant difference between these two subgroups ($p = 0.35$).

Embolic protection device

Three studies reported on data regarding the CAS technique without the use of protection device^{27,44,51}. The CEA group (15.2%, 34/223) presented significantly lower rates of new ischemic cerebral lesions compared to CAS (44.5%, 57/128) (OR: 0.16, 95% CI: 0.05-0.54, $p < 0.001$). The heterogeneity was substantial ($I^2 = 74.74\%$) (**Supplemental Figure 10**). Data concerning the CAS technique with the use of embolic protection device were extracted from 19 studies^{27,33,40,42,43,45–47,49,51–56,58,59,62,63}. The CEA group (11.9%, 167/1403) presented significantly lower rates of new ischemic cerebral lesions compared to CAS (40.7%, 454/1116) (OR: 0.21, 95% CI: 0.14-0.34, $p < 0.001$). The statistical heterogeneity remained substantial ($I^2 = 73.64\%$) (**Supplemental Figure 10**). There was no statistically significant difference between these two subgroups ($p = 0.65$).

Meta-regression analysis

The presence of pre-operative symptoms was expressed as the difference in rates of occurrence in the CEA versus the CAS group, and data were extracted from 19 studies^{27,40,44–47,49,51–59,61–63}. Meta-regression analysis revealed that the presence of pre-operative symptoms had no statistically significant influence on the incidence of new cerebral ischemic lesions ($p=0.241$) (**Supplemental Figure 11**). The data regarding hypertension were available in 15 studies^{27,40,44–46,48,51,52,54–57,59,62,63}, and no statistically significant influence was found in the presence of hypertension and the rate of newly detected lesions ($p=0.134$) (**Supplemental Figure 12**). The occurrence rates of diabetes and smoking were extracted from 15 studies^{27,40,44–46,48,51,52,54–57,59,62,63} and 13 studies^{27,40,44–46,51,52,56,57,59,61–63}, respectively, and no statistically significant influence was detected between smoking ($p=0.913$) and diabetes ($p=0.881$) in the incidence of new cerebral ischemic lesion (**Supplemental Figure 13 and Supplemental Figure 14**).

Discussion

Our study included a total of 25 studies reporting on new cerebral ischemic lesions after 1827 CEA procedures and 1500 CAS interventions. The results of this meta-analysis suggest that the incidence of new cerebral ischemic lesions was significantly lower in the CEA group compared to CAS regardless the time of MRI assessment. To address the heterogeneity between studies, we performed subgroup analyses based on the type of the study, RCTs or PSM and non-randomized, and the incidence of new lesions remained significantly higher after CAS. Moreover, the use of embolic protection device within the CAS procedure did not change the direction of the results, indicating significantly lower rates of new ischemic lesions after CEA.

The results of this study are in accordance with the previous meta-analysis of Gargiulo G et al., which is reporting on total 2014 procedures, and suggest slightly higher rates of incidence of new lesions in cerebral MRI (13.7% vs 12.2% in CEA and 41.1% vs 40.3% in CAS)¹⁵.

Furthermore, the meta-analysis of Schnaudigel S et al. included only studies that performed the MRI within 72 hours after the intervention¹⁴. This methodological approach does not allow to address the entirety of the available in the literature data concerning the new cerebral ischemic lesions. This might explain the low comparable rates of stroke events between CEA and CAS. They also included studies without direct comparison between the two techniques. The statistical analysis of these data seems to be inaccurate due to inadequate control of heterogeneity among the patients involved. Moreover, the previous meta-analysis of Traenka C et al., including 19 comparative studies, suggests a lower incidence of new cerebral ischemic lesions after CEA (10.6%, 118/1107) and CAS (40.4%, 401/993)¹³. The use of the fixed effect model for the calculation of the pooled effect may account for the slightly lower incidence observed in these findings compared to the results from our most updated meta-analysis with a total of 25 studies and incidence rates 13.7% (251/1827) and 41.1 (616/1500) after CEA and CAS, respectively.

Our study is the first to address the time variable, reporting on the interval between the operation and the subsequent MRI performance. Interestingly, the incidence of the new lesions within the first day following the revascularization (14.3% in CEA vs 41.3% in CAS) remains almost unchanged compared to 72 hours (13.6% in CEA vs 40.4% in CAS) and 1 week post-operatively (13.7% in CEA vs 41.1 in CAS). Our metanalysis is also the first to report on the contralateral cerebral ischemic lesions and the subgroup analysis concluded in lower rates after CEA compared to CAS. Embolic events could have occurred at any point during the revascularization, including angiography preceding CAS^{64,65}. The dislodgment of thrombotic material or atherosclerotic debris during the stenting procedure, with the manipulation of the catheters, the sheaths and the guidewires in the supra-aortic arch section, seems to give rise to single or multiple emboli, leading potentially to the presence of lesions in MRI, even in the contralateral arterial distribution⁶⁶. This may be an insight that a percentage of microemboli during CAS are

indeed deriving from arch manipulations, and thus their distribution is bilateral; further research will shed some light upon this fact.

A substudy of the International Carotis Stenting Study (ICSS)⁶⁷, reporting on the MRI findings, suggests an incidence 22.5% of stroke or transient ischemic attack in patients with new cerebral lesions in MRI versus 8.8% in patients without such lesions, following CAS²⁶. The respective rates following the CEA were 11% versus 9%, during 5 years of follow up. The above results suggest that the silent micro-embolism detected on early MRI after CAS may indicate a higher risk of cerebrovascular events²⁶. However, the ICSS included only patients with symptomatic carotid stenosis⁶⁷. The impact of periprocedural MRI lesions in carotid revascularization in pre-operative asymptomatic patients on the risk of cerebrovascular events remains still unknown⁵. Likewise, the study of Traenka C et al., using a complex and controversial statistical methodology⁶⁸, indicates a strong correlation between new cerebral ischemic lesions in the MRI and the probability of post procedural stroke event, in the combined CEA and CAS procedures¹³. The lack of adequate data within the studies included in our analysis prevents us from investigating the impact of the new cerebral ischemic lesions on the post-procedural clinical events and cognitive impairment.

To address the heterogeneity in CAS procedure concerning the use of an embolic protection device, we performed a subgroup analysis. The results of this analysis suggest slightly lower rates of new ischemic cerebral lesions following the implementation of an embolic protection device, with rates of 40.7% compared to 44.5% without any protection device. It is important to highlight that microemboli still can overcome embolic protection devices. The meta-analysis of Traenka C et al reports lower rates of occurrence of ischemic lesions, following the CAS technique, 36.8% with protection versus 37.1% without protection device¹³. In any case, the incidence of silent microembolism remains statistically significantly lower irrespective of whether an embolic protection device was used or not. Our findings appear to align also with the reported incidence of

37% of the CARENET Trial (Carotid Embolic Protection Using MicroNet)⁶⁹. The aforementioned result may indicate that the dislodgement of embolic particles is not adequately prevented by the use embolic protection device. Interestingly, recent prospective multicentre study concerning the CGuard MicroNet-covered Embolic Prevention System reported 19.6% new ischemic microembolisation in MRI performed within 72 hours post intervention⁷⁰. The limited available data concerning the stent type in the CAS group prevents us from proceeding to further analysis regarding the new cerebral ischemic lesions in these subgroups.

The preoperative cardiovascular risk along with the characteristics of the atherosclerotic plaque and the severity of stenosis are both unknown and imbalanced between the two groups. To address this issue, a subgroup analysis of RCTs and non-randomized was performed, and the findings are consistent with the overall result, indicating a lower incidence of new cerebral lesions following CEA. Furthermore, the meta-regression analysis concerning the pre-operative symptomatic status, hypertension, smoking and diabetes did not show a significant impact of these moderators in the difference of the incidence between the two techniques. These results are in accordance with the findings of a non-randomized study addressing symptomatic carotid stenosis treated with CAS, which demonstrated no correlation between these variables and the presence of cerebral ischemic lesions⁷¹. One retrospective study indicated the diabetes mellitus as a predictor of perioperative stroke or death among patients undergoing CEA, whereas it did not exhibit the same predictive significance among patients undergoing CAS⁷².

The limitations of the research should be acknowledged. First, there were the inherent limitations of a study-level meta-analysis as we did not have access to patient-level covariates that could confound our findings. Most of the studies do not mention many important periprocedural data that could affect the final outcomes: the rate of pre-existing contralateral carotid stenosis, use of eversion technique, shunting, the clamping duration and the operation time, and the hemodynamic parameters. Moreover, it is noteworthy to mention that variations in magnetic field

strengths may have contributed to differences in the sensitivity of detecting small ischemic brain lesions. In addition, there is inadequate information regarding the volume and the number of the lesions. Furthermore, the 22 of the 25 included studies are not randomized. The lack of randomization, allocation concealment, and blinding increases the chances of confounding and selection bias. Considering that CAS is usually performed on high-risk patients, the reported results may not be generalizable to other patients with intermediate surgical risk. Likewise, all the procedures in the included studies were performed in different centers by different operators. This fact, along with differences in the follow-up schemes across the studies, might have affected the generalizability of our results.

Conclusions

This meta-analysis indicates that CEA is associated with a significantly lower incidence of new cerebral ischemic lesions in early post-operative MRI, compared to CAS, regardless of whether they are ipsilateral or contralateral to the respective carotid artery. Embolic protection devices did not alter the outcome. The clinical importance of the incidence of silent cerebral microemboli as predictive factors for post-operative clinical outcomes along with emerging stenting techniques and types, remains to be defined.

Abbreviations: CEA: Carotid endarterectomy; CAS: Carotid Artery Stenting

*MRI was available in 49 procedures, 28 CEA and 21 CAS

**MRI was performed in 58 procedures, 30 CEA and 28 CAS

PRISMA 2020 flow diagram for new systematic reviews which included searches of databases, registers and other sources

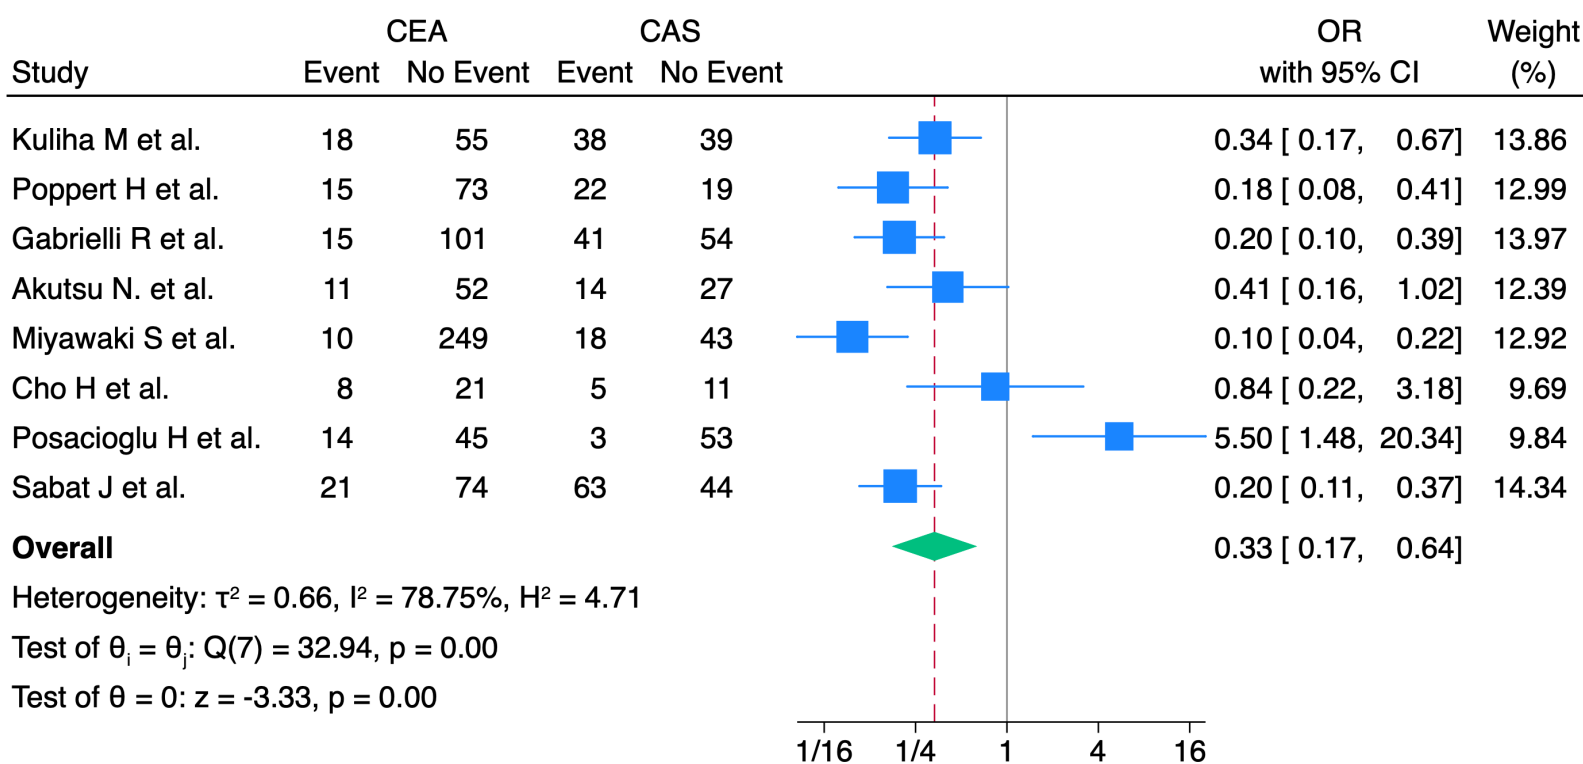

*Consider, if feasible to do so, reporting the number of records identified from each database or register searched (rather than the total number across all databases/registers).

**If automation tools were used, indicate how many records were excluded by a human and how many were excluded by automation tools.
