ABSTRACT

Background: *in vitro* studies show that goat milk proteins form less compact coagulates in the stomach compared to cow milk proteins. This may increase the accessibility of the proteins to digestive enzymes, thereby resulting in enhanced gastric digestion and amino acid (AA) absorption. However, this needs to be confirmed *in vivo* in humans.

Objective: This study aimed to examine gastric digestion and amino acid concentrations of cow milk-derived casein (cow MC) and goat milk-derived casein (goat MC).

Methods: In this single-blind randomized cross-over study 18 men (age 23 ± 1.6 years, BMI 23 ± 1.6 kg/m²) consumed 300 ml of a drink containing either 30 g of cow MC or goat MC. Participants underwent gastric MRI scans at baseline and t = 3, 10, 20, 30, 40, 50 and 60 minutes after the start of consumption. Blood samples were drawn at baseline and up to 4 hours postprandially to determine AA concentrations. In addition, participants verbally rated their appetite after each MRI measurement. Primary outcomes were gastric emptying and AA concentrations. The secondary outcome was gastric coagulation as inferred by image texture measures.

Results: Gastric emptying half-time was 80 ± 25 minutes for goat MC and 85 ± 24 minutes for cow MC (p = 0.395). In line with this, gastric emptying of the drinks over time was similar (MD 0.77, 95% CI [-6.9, 8.5], p = 0.845). Serum essential AA (MD -110 µmol/L, 95% CI [-162, -58]) and branched chain AA (MD -65 µmol/L, 95% CI [-101, -29]) were significantly higher over time for cow MC (both p < 0.001). The image texture measure contrast was significantly lower for the cow MC compared with the goat MC drink (MD 0.010, 95% CI [0.001, 0.020], p = 0.036).

Conclusion: Cow MC and goat MC have different coagulating properties, as measured by AA concentrations and supported by image texture analysis. This possible difference in
coagulation did not influence overall gastric emptying or the emptying of the liquid and coagulated fractions, which were similar. This warrants further research to examine differences in casein coagulation in vivo in the food matrix of milk products to help determine the optimal use for cow and goat milk and their protein fractions.
INTRODUCTION

Protein is an essential macronutrient used in many processes in the human body (Atherton and Smith 2012, Do, Lewis et al. 2019). It is important that ingested protein is properly digested and absorbed so that it can be used for protein synthesis (Mahé, Roos et al. 1996, van Vliet, Burd et al. 2015, Fardet, Dupont et al. 2019). Dairy products constitute a significant protein source globally (Lagrange, Whitsett et al. 2015). Cow milk dairy products are the most commonly used, but goat milk popularity is increasing (Miller and Lu 2019). One of the reasons for this is the consumer’s perception of its health benefits. These health benefits are hypothesized to originate from a difference in the milks’ digestion due to their different casein composition (Roy, Moughan et al. 2022).

Cow and goat milk generally contain about 3.5% protein of which caseins represent about 80% and whey proteins about 20% (Ceballos, Morales et al. 2009). During digestion in the stomach casein micelles (CM) are destabilized by pepsin proteolysis and acidification. This results in the formation of coagulates containing protein, and if present, fat globules (Ye, Liu et al. 2019). The physical properties of these casein coagulates could affect gastric protein digestion, gastric emptying and subsequent intestinal digestion and absorption of amino acids (AA) (Hupperz and Chia 2021). Previous studies, predominantly in vitro, have shown that casein coagulation is affected by several factors including processing-induced protein modifications, overall product composition (food matrix), and differences in protein composition for instance between animal species (Almaas, Cases et al. 2006, Ceballos, Morales et al. 2009, Wang, Ye et al. 2018, Mulet-Cabero, Mackie et al. 2019, Eijnatten, Roelofs et al. 2023, Hettinga, Pellis et al. 2023). Human in vivo studies on protein
modifications, resulting in different cow casein forms, showed that coagulation and gastric
emptying can have strong effects on the postprandial rise in AA bioavailability (Trommelen,
Weijzen et al. 2020). Even though goat micellar casein seemed to have similar protein
structures on an molecular level in an in vitro study using X-ray scattering (Ingham,
Smialowska et al. 2018), casein micelles differ in size, hydration, and mineralization
compared to bovine caseins (Claeys, Verraes et al. 2014, Roy, Moughan et al. 2022). During
static in vitro digestion, more β-casein and less αs1-casein may contribute to the formation
of looser gastric clots in goat casein micelles and therefore greater proteolysis than cow
casein micelles (Zhang, Liu et al. 2023). Increased access of the enzymes to the proteins
might lead to faster gastric digestion of goat as compared to cow milk-derived caseins and
milk, as seen in in vitro coagulum analysis (Park 2017). In line with this, infant formula based
on goat milk formed smaller flocs of aggregated protein and oil droplets under gastric
conditions, leading to faster protein digestion in goat milk infant formula than seen in cow
milk based infant formula (Ye, Cui et al. 2019). Similarly, goat milk proteins were digested
faster than cow milk proteins in in vitro digestion by human gastric and duodenal enzymes
(Almaas, Cases et al. 2006). This was also seen in two in vitro studies under simulated infant
conditions where proteins in goat milk and goat milk-based infant formula (IF) had different
digestive behaviour compared to those present in cow milk and cow milk-based formula
for gastric emptying, therefore differences in digestion concentrations were probably due to
differences in coagulation. However, not all studies showed a faster digestion of goat milk
protein. Inglingstad et al. found in an in vitro study that more goat milk casein remained
undigested after 30 min of digestion compared to cow milk casein (Inglingstad, Devold et al.
2010).
Since most research has been done \textit{in vitro} and results are not fully conclusive, they need to be verified \textit{in vivo} in humans. Understanding coagulation and gastric emptying of cow and goat milk proteins is important, since they may influence AA concentrations.

In summary, \textit{in vitro} results suggest that the differences in digestion between cow and goat milk are due to differences in casein. Therefore, the current \textit{in vivo} study aimed to quantify gastric digestion and absorption of cow and goat milk-derived casein \textit{in vivo} in humans. We used MRI to evaluate intragastric processes and gastric emptying and examined blood AA concentrations. We hypothesized that goat milk-derived casein has different coagulum characteristics, faster gastric emptying and higher AA concentrations in the blood compared to cow milk-derived casein.

\textbf{METHODS}

\textbf{Design}

The study was a randomized cross-over study in which healthy men underwent gastric MRI scans before and after consumption of 300 ml of a cow milk-derived-casein (cow MC) or goat milk-derived-casein (goat MC) drink. Primary outcomes were gastric emptying (measured by gastric emptying half time (GE-t50) and gastric volume over time) and serum AA concentrations. The secondary outcome was gastric coagulation. Tertiary outcomes were serum glucose, insulin, free fatty acids (FFA) and triglyceride (TG) concentrations and appetite ratings (hunger, fullness, desire to eat, prospective consumption and thirst). The study was conducted according to the principles of the Declaration of Helsinki (October
2013) and registered with the Dutch Trial Register under number NL8137 (accessible through
https://onderzoekmetmensen.nl/en/trial/28580). All participants signed written informed
consent.

Sample size

Sample size was calculated based on the primary outcomes, gastric emptying and post
prandial AA profile. Given our previous work on gastric emptying of caloric liquids in adults,
we know that the gastric emptying half time of 500 ml dairy-based shakes differing in energy
density and viscosity (protein content either 6 or 30 g and energy density 0.2 kcal/ml or 1
kcal/ml) has an overall gastric emptying half-time (GE-t50) of 54.7 ± 3.8 min, with the
different shakes ranging between 26.5 ± 3.0 min and 81.9 ± 8.3 min. The goat MC drink
contains 0.58 kcal/ml. Based on nutrient density the expected SD of the cow MC and the
goat MC drinks should be somewhere between 3 and 6. Therefore, we assumed an SD of 6
min for both drinks. In Camps et al. 2016 the average difference in GE-t50 between a 500-ml
thin and thick shake was 14.5 (low-calory) and 12.4 min (high-calory). For a 300-ml load the
GE-t50 will be smaller. We considered a 4 min difference in gastric emptying half-time
between the treatments as the minimum detectable difference. A two-sided test was
deemed appropriate, with Zα=1.96, p=0.05 and a power of 90% gives a Zβ of 1.28. Combined
with the SD of 6 this leads to the following formula for paired comparisons (Gogtay 2010): n
= (1.96 + 1.28)² x (6/4)² x 2 = (3.24)² x 1.5 = 18 participants.

To ensure sample size was sufficient for the other primary outcome, post prandial AA profile,
a second sample size calculation was performed. A priori sample size was estimated for both
primary outcomes, i.e. AA absorption concentrations and gastric volume over time. The estimation for postprandial AA was based on the peak value and the total free AA assessed in the serum after consumption of protein products. For the peak value, a difference of 100 µg/mL was regarded as relevant with an individual difference in peak values of 100 µg/mL (Farnfield, Trenerry et al. 2009, He, Spelbrink et al. 2013). Again we used a two-sided test, with $Z_\alpha=1.96$, $p=0.05$ and power of 90% gives a $Z_\beta=1.28$. This leads to the following formula for paired comparisons: $n = (1.96 + 1.28)^2 \times (100/100)^2 = (3.24)^2 \times 1 = 11$ participants. Based on the above, we aimed to include 18 participants.

Participants

Healthy males were recruited from November 2019 until March 2020 via e-mail using a database of individuals who expressed interest in participating in scientific research. Healthy, non-smoking men with a BMI of 18.5-25 kg/m² were included. Exclusion criteria were cow or goat milk allergy or lactose intolerance (self-reported), gastric disorders or regular gastric complaints, use of proton pump inhibitors or other gastric medication, or a contra-indication to MRI scanning (including, but not limited to pacemakers and defibrillators, intraorbital or intraocular metallic fragments ferromagnetic implants or being claustrophobic). Eighteen healthy men (age $23 \pm 1.6$ y, BMI $23 \pm 1.6$ kg/m²) participated in the study. The flow diagram can be found in Supplemental figure 1.

Treatments

Treatments were 300 ml drinks containing 30 g of protein originating from cow micellar casein concentrate powder (FrieslandCampina Refit MCI80) or 30 g goat micellar casein.
concentrate powder (Ausnutria, pilot plant). The drinks were matched on caloric content, protein, lactose and dry matter content. The amount of the AA leucine was equal. Vanilla extract was added to ensure similarity of taste. The drinks were prepared by slowly reconstituting the caseins at 50°C and thereafter allowing them to fully rehydrate at 4°C overnight using magnetic stirrer. This method assured a more similar viscosity in the drinks (when resolving fast by shaking there was a larger viscosity of the cow MC drink: 200-500 mPa.s and goat MC drink 8-15mPa.s). Three samples of each drink were measured with a rheometer to assess their viscosity using an Anton Paar Physica MCR 301 rheometer equipped with a Couette geometry with a volume of 1 mL. Viscosity was determined at constant shear rate of 100s-1 at 20°C. The difference in viscosity of the drinks (15.9 ± 3.9 mPa.s for the cow MC drink and 7.2 ± 1.8 mPa.s for the goat MC drink) was deemed not physiologically relevant (for instance milk 2 mPa.s vs yoghurt 150 mPa.s is a much larger and more relevant difference).

The composition per 300 ml serving of the cow MC drink was 176 kcal, 30 g protein, 90:10 casein to whey ratio, 12 g lactose, 0.77 g fat and 81 g dry matter. For the goat MC drink this was 174 kcal, 30 g protein, 90:10 casein to whey ratio, 12 g lactose, 0.60 g fat, 81 g dry matter. The amino acid profiles of the drinks can be found in Table 1. The data were analyzed by Qlip B.V. (lactose, dry matter, fat, protein) and NIZO (casein-to-whey ratio, only for goat micellar casein concentrate, for cow micellar casein concentrate the 90:10 casein to whey was stated by the supplier on the product data sheet).
**Study procedures**

Participants arrived after an overnight fast. Eating was allowed until 8 PM on the day before the study and drinking water was allowed up to one hour before the visit. Participants started their scan session at 8 or at 10 AM and were measured at the same time on both study days. First, a canula was placed in an antecubital vein. Then, participants verbally provided baseline appetite ratings after which the baseline MRI scan was performed and the baseline blood sample was drawn. Subsequently, they consumed one of the 300 ml drinks within two minutes. Participants were randomly allocated by block randomization using randomizer.org to receive either the cow or goat MC first and participants were blinded for which drink they received. Gastric MRI scans were performed at baseline and at t = 3, 10, 20, 30, 40, 50 and 60 minutes after the start of ingestion. During the MRI session participants verbally rated hunger, fullness, prospective consumption, thirst and nausea on a scale from 0 (not at all) to a 100 (most imaginable) at each time point (Noble, Clark et al. 2005, Blundell, de Graaf et al. 2010). A cut off of 10% is usually used as a meaningful difference (Flint, Raben et al. 2000). An overview of a test session is given in Figure 1.

**MRI**

Participants were scanned in a supine position with the use of a 3 Tesla Siemens Verio MRI scanner (Siemens AG, Munich, Germany) using a $T_2$-weighted spin echo sequence (HASTE, 24 6-mm slices, 2.4 mm gap, 1.19 x 1.19 mm in-plane resolution, TR 850 ms, TE 87 ms, flip angle 112 °C) with breath hold command on expiration to fixate the position of the diaphragm and the stomach. The duration of the scan was approximately 18 seconds. The software Medical Imaging Processing And Visualization (MIPAV, version 11.0.3) (McAuliffe, Lalonde et al. 2001)
was used to manually delineate gastric content on each slice and create a mask. Gastric content volume on each time point was calculated by multiplying surface area of gastric content per slice with slice thickness including gap distance and summing up the volumes of all slices showing gastric content. In Matlab a bias field correction was performed using multiplicative intrinsic component optimization (MICO) (Li, Gore et al. 2014). To assess changes in gastric coagulation, image texture analysis of the stomach content was performed using the masks in the software LIFEx (version 7.2.0, Institut national de la santé et de la recherche médicale, France) (Nioche, Orlhac et al. 2018). Homogeneity, coarseness, contrast, and busyness were calculated. These image metrics provide information on the spatial patterns of voxel intensity (Thomas, Qin et al. 2019). The Gray-Level Co-occurrence Matrix (GLCM) method was used for homogeneity (degree of similarity between voxels) and Neighborhood Gray-level Difference Matrix (NGLDM) difference of grey-levels between one voxel and its 26 neighbors in 8 dimensions was used for contrast (local variations), coarseness (spatial rate of change in intensity) and busyness (spatial frequency of changes in intensity). The number of grey-levels for texture metric calculation was set at 64, intensity rescaling at relative (ROI: min/max), and dimension processing at 2D. On each postprandial time point, texture metrics were calculated per slice for the stomach content. Subsequently, a weighted average texture metric was calculated based on the gastric content volume in each slice such that slices with little stomach content contributed less to the average than those with more stomach content. To quantify the (relative) volume of liquid and semi-solid stomach contents the number of lighter (more liquid), intermediate and darker (semi-solid) voxels was calculated by determining two intensity thresholds with the use of Otsu’s method (Otsu 1979) in Matlab (version R2023a, multithresh function), an approach previously used on in vitro and in vivo MRI images of gastric milk digestion (Mayar, Smeets et al. 2023, van
Eijnatten, Camps et al. 2023, Mayar, de Vries et al. 2024). The number of intermediate and
darker voxels were summed and interpreted as reflecting voxels in which coagulation took
place. This was done because visual inspection of the thresholding results using one
threshold showed a poorer separation between lighter and darker gastric contents. In the
context of this study, changes in image texture metrics were interpreted as reflecting
changes in the degree of coagulation. An example of stomach contents with and without
coagulation and their corresponding image texture measures can be found in Supplemental
figure 2.

Blood parameters

Blood samples were collected at baseline and at $t = 15, 30, 60, 90, 120, 180$ and $240$ min in
sodium-fluoride (for glucose), serum (for AA, FFA and insulin) and lithium-heparin (for
triglyceride) tubes. After collection, blood in the serum tube was allowed to clot for 30
minutes. Subsequently, all tubes were centrifuged at 1300 g for 10 minutes at 20 °C. After
centrifugation, the supernatant was divided into aliquots and stored in a –80°C freezer until
analysis. AA, FFA and insulin concentrations were measured at Wageningen University.
Glucose and TG concentrations were measured at the clinical chemistry lab of the Gelderse
Vallei hospital (Ede, The Netherlands).

AA concentrations were determined using triple quadrupole mass spectrometry (TQMS),
with an internal standard and $^{13}$C reference mix. Glucose concentrations were determined
using an Atellica CH Glucose Hexokinase_3 (GluH_3) assay kit and Atellica CH analyzer
(Siemens Healthineers, Netherlands). The lower limit of detection (LLOD) was 0.2 mmol/l
and intra-assay CVs were at most 4.5%. Serum insulin concentrations were determined using
an enzymatic immunoassay kit (ELISA, Mercodia AB, Sweden) with a LOD of 0.008 mmol/l
and intra-assay CVs of maximal 6.9%. Serum FFA concentrations were determined using an
enzymatic assay kit (Instruchemie, Delfzijl) with a LOD of 4 mg/dl and intra-assay CVs of at most 1.4%. TG concentrations were quantified using an Atellica CH TG enzymatic assay kit and
quantified using an Atellica CH analyzer (Siemens Healthineers, Netherlands) with a LOD of 8
mg/dl and intra-assay CVs of at most 1.0%.

**Statistical analysis**

In order to estimate GE-t50, a commonly used summary measure, a curve was fitted to the
gastric volume over time of the cow MC and goat MC drink using R statistical software
according to the linear-exponential model as developed on the basis of earlier models
(Elashoff, Reedy et al. 1982, Fruehauf, Menne et al. 2011). Further analyses were performed
in SPSS (version 22, IBM, Armonk, USA). Essential amino acid (EAA), non-essential amino acid
(NEAA) and branch-chained amino acid (BCAA) concentrations were calculated by adding
individual AA concentrations. GE-t50 was compared between cow MC and goat MC drink
with a paired t-test. Normality was confirmed by inspecting QQ plots of the residuals. Overall
gastric volume, coagulation (image texture of the gastric contents as reflected in
homogeneity, contrast, coarseness and busyness), blood parameters and appetite ratings
over time were tested using linear mixed models with treatment, time and treatment * time
as fixed factors and baseline values as covariate. Post-hoc t-tests were performed with
Tukey's correction when treatments were significantly different. In addition, Pearson
correlation coefficients were calculated for the associations between coagulation (image
texture metrics at 30 minutes, chosen because 30 min was the first time point that
cogulation was clearly visible) and blood parameters (EAA, NEAA, BCAA, glucose and
insulin). The significance threshold was set at $p = 0.05$. Data are expressed as mean ± SD
unless stated otherwise.

RESULTS

Gastric emptying

The curves of gastric emptying over time of cow MC and goat MC drink is shown in Figure 2.
Gastric emptying half-time was $84.6 ± 23.7$ minutes for the cow MC drink, compared to $79.8 ± 24.7$ minutes for the goat MC drink ($p = 0.395$). Furthermore, the mixed model analysis showed no difference in gastric emptying over time between the drinks (MD 0.77, 95% CI [-6.9, 8.5], $p = 0.845$) and there was no interaction effect of time*treatment ($p = 0.65$). Time effect was significantly different ($p < 0.001$).

An example of a thresholded stomach image can be found in Supplemental figure 3. The percentage of volume of liquid and coagulum did not differ between the cow MC and goat MC drink over time (coagulum: MD 0.407 %, 95 % CI [-1.2, 2.0], $p = 0.607$) and there was no interaction effect of treatment*time ($p = 0.52$). There was a significant decrease in coagulated volume over time (time effect $p = 0.002$).

Amino acids

Figures of serum EAA, NEAA and BCAA can be found in Figure 3. Figures of all individual AAs can be found in Supplemental figure 4 and 5. Serum concentration of EAA over time was
lower for goat MC (MD -110 µmol/L, 95% CI [-162, -58], p < 0.001). Post-hoc t-test showed
that this difference was driven by time points t = 30 (p = 0.002) and t = 180 (p = 0.025) and
that there tended to be a lower serum concentration of NEAA for goat MC over time (MD -
62.1 µmol/L, 95% CI [-127, 3.4], p = 0.063), driven by time point t = 180 min (p = 0.045).
Serum concentration of BCAA was also lower for goat MC (MD -65 µmol/L, 95% CI [-101, -
29], p < 0.001). This was driven by time point t = 30 (p = 0.005), and there was a trend at t =
180 (p = 0.051). Time effects were significant for EAA, NEAA and BCAA (p < 0.001) and
there were no interaction effects.

Coagulation

Figure 4 shows examples of MRI images showing cross-sections of the abdomen at the level
of the stomach showing homogenous stomach content after casein drink consumption and
later coagulum formation.

The curves of the image texture metric contrast calculated over the stomach content over
time can be found in Figure 5. The other image texture metrics can be found in
Supplemental figure 6. The texture metric contrast was significantly lower in the cow MC
drink than the goat MC drink (MD 0.010, 95% CI [0.001, 0.020], p = 0.036). Homogeneity
(MD -0.003, 95% CI [-0.012, 0.006], p = 0.503), coarseness (MD 0.001, 95% CI [0.000, 0.001],
p =0.310) and busyness (MD -0.008, 95% CI [-0.023, 0.007], p = 0.315) were not significantly
different between the drinks. Time effects were significant for all texture metrics (p <
0.001) and there were no interaction effects.
Glucose and insulin

Overall, glucose concentrations did not differ between the drinks (MD -0.055 mmol/L, 95% CI [-0.14, 0.028], p = 0.19). Only when examining specific timepoints, glucose concentration for the goat MC drink was slightly higher compared to the cow MC drink at t = 30 minutes (MD 0.015 mmol/L, 95% CI [0.42, 0.22], p=0.036). Insulin concentrations did not differ between cow MC and goat MC drinks (MD -1.66 mIU/L, 95% CI [1.35, -0.16], p = 0.84) (graphs in Supplemental figure 7). Time effects where significant for glucose and insulin (p < 0.001) and there were no interaction effects.

Triglycerides and free fatty acids

FFA concentrations were not different between the cow MC and goat MC drinks (MD -0.032 mmol/L, 95% CI [0.034, 0.001], p = 0.948). TG concentrations over time were significantly higher for goat MC (MD 0.074 mmol/L, 95% CI [0.039, 0.109], p =0.009), even with baseline differences as a covariate in the mixed model analysis. There were no differences for any of the time points (graphs in Supplemental figure 8). Time effects where significant for FFA and TG (p < 0.001) and there were no interaction effects.

Appetite ratings

Hunger and thirst did not differ between the treatments. Fullness, desire to eat and prospective consumption over time were significantly lower after goat MC ingestion (p = 0.036, p < 0.001, p < 0.001, respectively). However, as can be seen in Supplemental figure 9, the differences are small (below 10 units as a mean difference over time).
Correlations between image texture metrics, blood concentrations and gastric emptying

To explore the associations between image texture metrics as an indicator of the degree of coagulation, blood concentrations and gastric emptying, Pearson correlation coefficients were calculated for image texture metrics at 30 min (because at t=30 min coagulation was visible) and 4-h AUC of blood parameters (EAA, NEAA, BCAA, glucose and insulin). Overall, GE-t50 negatively correlated with contrast (r=-0.413, 95% CI [-0.662, -0.081]) and coarseness (r=-0.38, 95% CI [-0.640, -0.043]). NEAA correlated with insulin (r=0.491, 95% CI [0.152, 0.727]). When divided between treatments: goat MC, EAA, NEAA and BCAA were negatively correlated with coarseness (r=-0.698, 95% CI [-0.887, -0.175], r=-0.572, 95% CI [-0.837, -0.002] and r = -0.690, 95% CI [-0.891, -0.162] respectively). GE-t50 was positively correlated with insulin (r = 0.558, 95% CI [0.130, 0.790]). For cow MC GE-t50 was positively correlated with image homogeneity and busyness (r = 0.498, 95% CI [0.061, 0.760] and r = 0.568, 95% CI [0.141, 0.787] respectively) and negatively correlated with contrast and coarseness (r = -0.627, 95% CI [-0.822, -0.217] and r = -0.554, 95% CI [-0.780, -0.134]). All other correlations can be found in Supplemental figure 10.

DISCUSSION

This is the first study to explore digestion of cow and goat MC by quantifying gastric emptying, gastric casein coagulation and blood concentrations in humans. Overall, serum concentrations of EAA and BCAA were higher for cow MC over time. Gastric emptying curves and gastric emptying half-time (GE-t50) were similar for the cow MC and goat MC drinks. The image texture metric contrast was significantly different, suggesting a difference in
Coagulation. No significant differences between cow MC and goat MC were seen for blood
insulin, glucose and FFA concentrations. Serum TG concentrations were significantly higher
in goat MC.

Coagulation was visible on the MRI scans for both the cow MC and goat MC drinks (see
Figure 4). In an attempt to objectively quantify this, image texture metrics were calculated
for the stomach contents. It could for instance be hypothesized that a lower homogeneity
and higher contrast could mean ‘more’ coagulation. Even though the actual meaning of
differences in image texture metrics in reference to coagulating properties of stomach
content requires more research, the difference in the image texture metric ‘contrast’ does
support the notion of a difference in coagulation between cow MC and goat MC. However,
the metrics homogeneity, coarseness and busyness did not differ between the drinks. It
should be taken into account that higher homogeneity could not only reflect a homogenous
liquid, but also the presence of a large and fairly homogenous coagulum. Another aspect to
consider is that not only the size, but also the structure is an important characteristic of
coagula. For instance, some coagulates can be firm and have a greater weight and denser
structure than less dense coagulates with approximately the same volume (Wang, Ye et al.
2018). The image texture metrics could possibly be used to quantify the density of the
coagulum, as MRI can detect water content contained in the coagulum. Notably, MRI image
texture parameters are affected by the resolution of the input images and could detect
differences in image intensity patterns which is more sensitive than analyzing MRI images by
eye. This requires further validation by concomitant analysis of MRI images and coagulates
that differ in size and density. To provide molecular-level information, other MRI techniques
are being developed such as measurement of the magnetization transfer ratio and relaxation
rates (Deng, Seims et al. 2022, Deng, Mars et al. 2023, Mayar, Smeets et al. 2023). These measurements require additional MRI spectra to be recorded, but could be used in follow-up research to examine more subtle differences in protein coagulation in vivo.

Cow MC and goat MC coagulates likely differ, since in vitro and animal in vivo research showed that the consistency of the gastric coagulum changes as digestion progresses (Ye, Liu et al. 2019, Roy, Moughan et al. 2022). For instance, the recent research of Roy et al. showed that goat milk coagulum had a softer consistency and less fused protein networks, especially toward a later stage of digestion (Roy, Moughan et al. 2022). We hypothesized that this would lead to a longer gastric retention of coagulum in the cow milk treatment and relatively faster gastric emptying from goat milk casein in comparison to cow milk casein, as previously seen in animal in vivo work (Roy, Moughan et al. 2022) and human in vivo work (van Eijnatten, Roelofs et al. 2024). However, we observed that the overall gastric emptying was similar and the emptying of coagulum and liquid volume fraction did not differ between cow MC and goat MC. This is in line with recent findings where coagulation differences did not affect GE, but did affect AA concentrations (Milan, Barnett et al. 2024).

As expected, AA concentrations differed between casein derived from these two species, likely due to the differing coagulation properties of cow MC and goat MC. Goat milks’ softer and smaller coagulates (Park 2017) would make the proteins more accessible to digestive enzymes (proteases) and allow these enzymes to more efficiently break down peptide bonds so that goat milk proteins would be faster digested than cow milk proteins (Almaas, Cases et al. 2006). However, this study showed more serum AA in the 5 hours measured postprandial
in cow milk, which seems contradictive. On the other hand, in an in vitro study of Inglingstad et al., who used a two-step digestion model (gastric and duodenal), caseins from goat milk were less digested compared to caseins from cow milk during gastric digestion (Inglingstad, Devold et al. 2010). Interestingly, in our study serum EAA concentrations were higher for cow MC, while we expected higher concentrations for goat MC based on previous in vitro studies (Almaas, Cases et al. 2006, Zhang, Liu et al. 2023). However, we examined caseins in relative isolation where milk fat content was negligible and the mineral profile was different than casein micelles. The formation of coagulates interacts with minerals and fat and thus coagulation might be different for a whole food, also named ‘food matrix’ (Aguilera 2019).

For instance, the interaction of peptides with small fat globules can slow protein breakdown and thereby influence AA availability (Le Feunteun, Barbé et al. 2014, Tunick, Ren et al. 2016). A second factor leading to differences in coagulation might be the difference in buffering capacity between cow and goat milk. Goat milk contains a higher non-protein nitrogen (NPN) amount than cow milk and more NPN contributes to a 'slower' acidification in the stomach (Park 1991). Roy et al also discuss the high degree of variation in casein micelle characteristics within the same species. Within and across species differences in breeds, genetic variants, and phosphorylation sites of the caseins may also add to the variation (Crowley, Kelly et al. 2017, Roy, Moughan et al. 2022). In summary, to our knowledge three factors could have contributed to the discrepancies of our study with other studies: 1) the fact that this is the first human in vivo study on gastric digestion, 2) that we assessed casein outside of the food matrix, 3) the buffering capacity and the variation in casein characteristics even within species.
Fullness, desire to eat and prospective consumption were significantly lower for goat MC, but these differences were small. For instance, the mean difference of desire to eat had a mean difference of 7 pts over the 60 measured minutes. A difference of < 10% is usually not considered as practically relevant (Flint, Raben et al. 2000). This is in line with the lack of differences in gastric volume over time and coagulum volume over time between the drinks.

Future research could explore casein coagulation within a food matrix, as this study focused on assessing the gastric digestion of the casein fraction from both cow and goat milk. It is important to acknowledge that the food matrix significantly influences protein digestion, involving interactions with components like fat (Cecchinato, Penasa et al. 2012).

In conclusion, cow MC and goat MC show a difference in coagulation characteristics as measured by AA concentrations and supported by image texture analysis in vivo in humans. This difference in coagulation did not influence overall gastric emptying or the emptied fraction of the liquid and coagulum volume. Therefore gastric emptying was not the main driver of AA differences. This warrants further research to examine differences in casein coagulation in vivo in the food matrix and how this affects digestion of milk products, such as infant formula or medical nutrition. This may help to determine the optimal use for cow and goat milk and their protein fractions.

ACKNOWLEDGEMENTS
EE, GC, WR and PS designed the research; EE conducted the research. EE analysed the data and drafted the paper. GC, WR, LP and PS revised the manuscript critically for important intellectual content. PS had primary responsibility for final content. All authors read and approved the final manuscript. This study was funded by Ausnutria and WR and LP were employed by Ausnutria. All other authors declare no further conflict of interest. We thank Julia Roelofs, Mireille Schipper, Jip Jordaan and Lisa van den Berg for assisting with data collection and Jacques Vervoort and Sébas Wesseling for the amino acid analysis. The use of the 3T MRI was made possible by WUR Shared Research Facilities.

FIGURE LEGENDS

**Figure 1.** Overview of a test session

**Figure 2.** Mean ± SEM gastric content volume over time for the 300 ml cow (cow MC) and goat (goat MC) and milk-derived casein drinks. T=0 min is the start of ingestion. A linear mixed model analysis showed no significant difference between the drinks.

**Figure 3.** Mean concentration ± SD of (A) serum essential amino acid, (B) non-essential amino acid and (C) branch-chained amino acid concentrations after cow (cow MC) and goat (goat MC) milk-derived casein drink ingestion. *p < 0.05 placed at the right of the graph denotes a significant treatment effect. Above a data point it denotes a significant time point (post-hoc t-test).

**Figure 4.** Examples of T₂-weighted MRI images showing cross-sections through an empty stomach after an overnight fast (baseline) and after 300 ml casein drink consumption. At t = 30 and 60 min coagulation can be observed.

**Figure 5.** Mean ± SEM of the image texture metric contrast calculated over the stomach content over time after cow (cow MC) and goat (goat MC) milk-derived casein drink ingestion. A linear mixed model analysis showed a significant higher contrast of goat MC (p = 0.036) driven by t = 40 min as seen with a post hoc t-test. A higher contrast reflects a greater degree of structure in the image, which we interpret as a difference in coagulation.
