Validation of the GCS-Pupil scale in Traumatic Brain Injury

Incremental prognostic performance of pupillary reactivity with GCS in the prospective observational cohorts CENTER-TBI and TRACK-TBI

Abstract

Objective: To compare the incremental prognostic value of pupillary reactivity as captured in the GCS-Pupils score (GCS-P) or added as separate variable to the Glasgow Coma Scale (GCS) in traumatic brain injury (TBI).

Methods: We analyzed patients enrolled between 2014 and 2018 in the Collaborative European NeuroTrauma Effectiveness Research in Traumatic Brain Injury (CENTER-TBI, n=3521) and the Transforming Research and Clinical Knowledge in Traumatic Brain Injury (TRACK-TBI, n=1439) cohorts. We used logistic regression to quantify the prognostic performances of GCS-P versus GCS according to Nagelkerke's R^2. Endpoints were mortality and unfavorable outcome (Glasgow Outcome Scale-Extended score 1-4) at 6 months after injury. We estimated 95% confidence intervals with bootstrap resampling to summarize the improvement in prognostic capability.

Results: GCS as a linear score had a R^2 of 24% (95% confidence interval [CI] 17-30) and 30% (95%CI 17-43) for mortality and 29% (95%CI 25-34) and 38% (95%CI 29-47) for unfavorable outcome in CENTER-TBI and TRACK-TBI respectively. In the meta-analysis, pupillary reactivity as a separate variable improved the R^2 by an absolute value of 6% and 2% for mortality and unfavorable outcome (95%CI 4.0-7.7 and 1.2-3.0, respectively), with half the improvement captured in the GCS-P score (3%, 95%CI 2.1-3.3 and 1%, 95%CI 1-1.7, respectively).

Conclusions: GCS-P has a stronger association with outcome after TBI than the GCS alone. However, for prognostic models, inclusion of GCS and pupillary reactivity as separate scores is preferable.

Background

Traumatic brain injury (TBI) is a pressing, multifaceted health concern affecting millions of people worldwide annually.[1-3] The initial clinical severity of TBI is commonly reported according to the Glasgow Coma Scale (GCS), which is often trichotomized into three classes of severity: mild (GCS 13-15), moderate (GCS 9-12) and severe (GCS≤8). This tripartite division is embedded in clinical practice and research, but neglects patient experiences and the relevant heterogeneity within the divisions. Consequently, therapeutic nihilism may result in patients with presumed "severe" injuries, while disabling complaints and symptoms may be disregarded in patients with presumed "mild" injuries.[4,5,6] The NIH-NINDS has implemented an international initiative to develop a novel approach to TBI classification, culminating in a workshop in Bethesda, USA in January 2024.[7]

In preparation of this workshop, the working group on clinical assessment considered the relative value of using the full GCS or the GCS-Pupils score (GCS-P) for classifying the clinical severity of TBI. The GCS-P was proposed by Brennan and colleagues in 2018.[8,9] In this novel scale one point is deducted from the GCS score for each unreactive pupil, resulting in a score ranging from 1 to 15, which intuitively has merit. Both the GCS and pupillary reactivity serve as important features in surgical decision-making, and lower scores are associated with poorer outcome. Moreover, the GCS (or its motor component), and pupillary reactivity are important components of well validated multifactorial prognostic models, such as the International Mission for Prognosis and Analysis of Clinical Trials in TBI (IMPACT) and Corticosteroid Randomization after Significant Head Injury (CRASH) models.[10-12]

With the simplicity of the GCS-P being comparable to the GCS and the information yield potentially greater, it shows potential to better characterize TBI. Studies conducted on the IMPACT and CRASH datasets have shown that merging of GCS and pupillary reactivity into the GCS-P may have comparable information yield compared to using GCS and

pupillary reactivity as separate factors, but these were mainly focused on patients with moderate to severe TBI, and it is uncertain if this may hold across all severities.[8,9] Uncertainty further exists if a summary score like the GCS-P provides similar prognostic information as the inclusion of these features separately in a prognostic model. We aimed to analyze the association of GCS and GCS-P with outcome in large contemporaneous datasets including TBI of all severities and to explore their prognostic performance relative to each other and to a model including GCS and pupillary reactivity as separate prognostic factors.

Methods

Study population

This study used data from 2 large multicenter, prospective, observational cohorts: the Collaborative European NeuroTrauma Effectiveness Research in TBI (CENTER-TBI) and the Transforming Research and Clinical Knowledge in Traumatic Brain Injury (TRACK-TBI) studies.[13,14] CENTER-TBI included TBI patients between 2014 and 2017 presenting to one of 65 participating centers across Europe. TRACK-TBI enrolled TBI patients presenting to the emergency department between 2014 and 2019 from 18 United States (US) level 1 trauma centers through convenience sampling. CENTER-TBI and TRACK-TBI are registered on ClinicalTrials.gov (number NCT02210221 and NCT02119182 respectively).

All adults ($\geq$ 18 years) with a TBI recruited to these two studies were included in the current analysis. Exclusion criteria were: (1) missing baseline motor score or pupillary reactivity scorings or (2) missing Glasgow Outcome Scale-Extended (GOS-E) scores.

GCS(-P) & Pupillary reactivity

For CENTER-TBI, baseline GCS and pupillary reactivity were defined, using IMPACT methodology as the most recent not missing value between emergency room (ER) discharge (post-stabilisation) and pre-hospital assessment. Untestable eye (swelling) and verbal

(intubation) components of the GCS were imputed with the number "1".[15] In TRACK-TBI, the baseline GCS and pupillary reactivity were defined as the assessment at ER presentation. Missing eye and verbal components were imputed as follows:

In case only verbal score is untestable: Total GCS = 0.55+1.45*[eye]+1.44*[mot].

In case both Eye and verbal score is untestable: Total GCS = 0.6+2.4*[mot].

The GCS was analyzed as an ordinal scale starting at 3 (lowest score) and ending at 15 (highest score). Pupillary reactivity was expressed using the Pupil Reactivity Score (PRS) which is scored based on 3 levels, namely both reacting, one reacting and none reacting, resulting in a score of 0, -1 or -2. The GCS and PRS were combined into an integrated GCS-P score, according to predefined methodology in the initial GCS-P study, subtracting the PRS from the GCS, yielding scores from 1 to 15.[8]

Outcomes

Patient (long-term) functional outcome was expressed using the GOS-E scale at 6 months after injury. GOS-E is an extended measure used to quantify functional outcome and consists of an 8-point scale ranging from 1 (death) to 8 (upper good recovery).[16] The categories 2 (vegetative state) and 3 (lower severe disability) were merged as these could not be differentiated on assessments performed by postal questionnaire. In CENTER-TBI, missing outcomes at 6 months after injury were imputed using a multinomial model if assessments at one or more other time points were available. In TRACK-TBI, only patients with available GOSE scores at 6 months were included. The primary outcomes are unfavorable outcome, which was defined as a GOS-E score lower than "lower moderate disability" (<5) and mortality, defined as patient death within 6 months after injury.

Statistical analysis

Logistic regression modelling was used to analyze the relationships between GCS, PRS, GCS-P and patient outcome (GOS-E and mortality). Nagelkerke's pseudo R^2 was used as primary measure to quantify the prognostic capability of the included parameters.[17] Nagelkerke's R^2 is calculated at the log likelihood scale. It is a measure of how much better the model fits the data compared to a model with no predictors. Nagelkerke's R^2 can be interpreted as a measure of the proportion of variation explained in the dependent variable (the six-month outcome) that is explained by the independent variables (predictors) in a logistic regression model.[18,19] The uncertainty of the R^2 estimate was quantified by bootstrap resampling (5000 repetitions). We also estimated the increase in R^2, the ΔR^2, for GCS-P versus GCS models and GCS plus PRS versus GCS-P models within each bootstrap sample. The distribution of bootstrapped R^2 estimates was used to estimate 95% confidence intervals (CI) for R^2 and differences between R^2 estimates. A pooled estimate across the CENTER-TBI and TRACK-TBI studies was estimated with inverse variance weighting. The regression analyses yielded estimations of odds ratios (OR) and 95% CI. The OR indicates the odds of unfavorable outcome (over favorable outcome) per 1-point increase in the GCS, PRS or GCS-P scales.

A subgroup analysis was performed to assess the prognostic capabilities (mortality and unfavorable outcome) of GCS and GCS-P versus a model with both GCS and PRS in patients with moderate to severe TBI (GCS 3-12). Moreover, an additional age-stratified subgroup analysis was performed on 3 different age groups based on the age distribution in the cohorts, namely age <45, age 45-64, age ≥65 years.

Statistical analysis was performed using R version 4.1.2.[20]

Results

Demographics and baseline characteristics

The total CENTER-TBI and TRACK-TBI cohorts consisted of 4509 and 2552 patients respectively. Of those patients, 3521 from CENTER-TBI and 1439 from TRACK-TBI were eligible for primary analysis (Figure 1).

The included patients from both studies were similar in sex, median GCS, PRS and CT imaging variables such as the presence of epidural hematoma (EDH), acute subdural hematoma (ASDH), traumatic subarachnoid hemorrhage (tSAH) and diffuse axonal injury (DAI) (Table 1). TRACK-TBI patients were generally younger than CENTER-TBI patients (median age: 39 years vs 51 years, respectively). Furthermore, mild TBI was more frequent in TRACK-TBI (78%) patients compared to CENTER-TBI (67%). Moreover, cerebral contusions (36% and 25%, respectively) and midline shift (16% and 11%, respectively) were more prevalent in CENTER-TBI compared to TRACK-TBI respectively.

Distribution of outcomes

Mortality and unfavorable outcome were more frequent in CENTER-TBI (12% and 25%) versus TRACK-TBI (7% and 14%). However, there were no large differences in the distribution of unfavorable outcome and mortality per GCS and PRS and within GCS-P scores (Supplemental Table 1 & 2). In CENTER-TBI, a small decrease in mortality at both GCS and GCS-P = 7 and 8 was observed while mortality increased again at GCS and GCS-P = 9 (Figure 2). Moreover, low GCS-P (1-2) displayed higher percentages of mortality and unfavorable outcome compared to low GCS (3-4). Mild and moderate TBI displayed similar distributions (Figure 2). In TRACK-TBI, low GCS-P (1-2) displayed lower mortality percentages at 6 months compared to CENTER-TBI (Figure 2 and Supplemental Table 3).

Associations of GCS(-P) and PRS with outcome

The explained variance was higher for the regression model containing GCS and PRS (R^2 30% and 35%, Table 2) as separate predictors compared to the model containing GCS-P alone (R^2 27% and 33%) for mortality in both CENTER-TBI and TRACK-TBI respectively (Figure 3).

A model containing only GCS had the lowest model performance in CENTER-TBI and TRACK-TBI (R^2 24% and 30%, respectively). GCS had a lower range of predicted risk compared to GCS-P and GCS together with PRS (Supplemental Figure 1). Regarding unfavorable outcome, explained variance was highest in the model containing GCS and PRS as separate predictors compared to GCS-P in both CENTER-TBI and TRACK-TBI (GCS and PRS: R^2 32% and 40% & GCS-P: R^2 31% and 39%, respectively, Table 2). Moreover, a model containing only GCS had the lowest model performance in both cohorts (R^2 29 % and 38% for CENTER-TBI and TRACK-TBI respectively). In a meta-analysis across studies, pupils as a separate variable improved the R^2 by an absolute value of 6% and 2% for mortality and unfavorable outcome, with half the improvement captured in the GCS-P score (3% and 1%, respectively, Table 2, Figure 3 and 4).

For both cohorts, in a logistic regression model containing GCS, an incremental 1-point increase in GCS significantly decreased the odds for mortality within 6 months after injury (OR 0.79, 95%CI 0.77-0.81 and OR 0.75, 95%CI 0.72-0.79 for CENTER-TBI and TRACK-TBI respectively, Table 3). Similarly, more favorable GCS-P showed comparable odds ratios in both CENTER-TBI and TRACK-TBI (OR 0.79, 95%CI 0.77-0.81 and OR 0.76, 95%CI 0.73-0.79, respectively). In a model with both GCS and PRS, incremental 1-point decreases in PRS decreased the odds of mortality more strongly (OR 0.4, 95%CI 0.33-

0.45 and OR 0.43, 95% CI 0.32-0.58 for CENTER-TBI and TRACK-TBI, respectively) than the odds for GCS (OR 0.84, 95%CI 0.82-0.86 and 0.80, 95%CI 0.76-0.85).

When predicting unfavorable outcome (GOS-E 1-4) using comparable models, similar associations were found (Table 3). Again, in a model with both GCS and PRS, a poorer PRS was more strongly associated with a lower odds of unfavorable outcome in both CENTER-TBI and TRACK-TBI patients (OR 0.5, 95%CI 0.42-0.59 and OR 0.56, 95%CI 0.42-0.76, respectively) than a lower GCS score (OR 0.81, 95%CI 0.-0. and OR 0.77, 95%CI 0.-0., respectively).

Subgroup analysis

In the subgroup of 1161 patients in CENTER-TBI and 317 patients in TRACK-TBI with moderate and severe TBI (GCS 3-12), strong correlations were confirmed for both GCS-P, GCS and GCS and PRS with similar differences in explained variability (Supplemental Tables 4, Supplemental Figure 2). In the age-stratified subgroups, similar differences in explained variability between GCS-P, GCS and GCS and PRS were found, with greater explained variance in younger patients in CENTER-TBI and older patients in TRACK-TBI (Supplemental Table 4).

Discussion

This study confirmed that in all models explored, pupillary reactivity adds important prognostic information over the GCS. However, the usage of PRS and GCS alone attributed to the greatest increment in ΔR^2 for mortality and unfavorable outcome (5.8% and 2.1%), with half of this variance being captured by GCS-P (2.7% and 1.3%).

These results are largely in line with those reported in the original paper on GCS-P using the IMPACT and CRASH cohorts.[8] In these studies, the addition of PRS to GCS as

separate predictors in a regression model increased the ΔR^2 by 4% and 3.2% with a ΔR^2 of 3.4% and 2.2% between GCS and GCS-P for mortality and unfavorable outcome, respectively, leading the authors of the original paper to suggest that the GCS-P is a valuable summary score over the GCS alone. Both studies show an incremental advantage of the GCS and PRS as separate predictors across the broader spectrum of TBI included in the CENTER-TBI and TRACK-TBI studies. The replication of the seminal results of Brennan and colleagues in our study is remarkable in the presence of disparities between cohorts. A major difference is the fraction of mild TBI patients (GCS>8): 78% in CENTER-TBI and 67% in TRACK-TBI compared to 21% in the combined IMPACT and CRASH cohorts.[11] Our primary analysis included all TBI patients with available GCS, PRS and GOSE, and thus were inclusive also of patients with GCS 15. Furthermore, patients in the original IMPACT and CRASH cohorts were considerably younger compared to CENTER-TBI and TRACK-TBI, with the median age in CENTER-TBI over 20 years higher than the median age in IMPACT.[11] Pupillary abnormalities were also more common in the IMPACT cohort.

Subgroup analyses

We performed a subgroup analysis on patients with moderate and severe TBI (GCS 3-12) to improve comparability between our study and that of Brennan and colleagues[9,10]. Comparable to the primary analysis, similar trends were observed in the prognostic information from GCS, PRS and GCS-P, but differences in explained variance between groups were more pronounced in moderate and severe TBI (Supplemental Table 4). The age-stratified subgroup analysis displayed variance between age groups regarding explained variability by the logistic regression models, but comparable trends and ΔR^2 for the predictor variables in CENTER-TBI and TRACK-TBI

 Pros and cons of a summary score

Simplifications of the GCS inevitably convey less information and therefore loss of clinical value. Such considerations hold, for example, for the trichotomy of the GCS into mild, moderate and severe categories versus use of the full ordinal GCS sum score, but also to the GCS sum score compared to use of the underpinning eye, motor and verbal components, as their cumulative prognostic value is higher than that of the sum score alone.[21]

The integration of multiple clinical characteristics into a single score attempts to provide a single integrated articulation of TBI severity and status, without the loss of information. A careful consideration should be made whether any loss of information is acceptable in favor of utility and simplicity. A strength of the GCS-P is that it combines two of the most relevant clinical predictors for TBI into a summary score, and yet maintains the simplicity and ease of use of the GCS. Relative disadvantages include some loss of information compared to the use of GCS and PRS as separate predictors. Its utility as an overall parameter of injury severity is influenced by its "skewed" discrimination towards the high end of the severity spectrum. However, the subtraction of PRS from the GCS across the entire GCS range potentially reduces efficacy when non-reactive pupils occur at higher GCS scores. Therefore, GCS-P mainly provides additional value in patients with moderate to severe TBI which is in line with the index study by Brennan and Teasdale and the current study. Any decision about the use of an integrated score must also be balanced against potential implementation barriers, which may be substantial when introducing a modification of the GCS, which is deeply embedded in clinical practice.

Finally, different contributions from pupillary unreactivity and motor responses may add up to identical GCS-P scores but may have widely different clinical import and outcome. For example, a patient with a GCS of 3 and two reactive pupils (GCS-P = 3) may indeed have a very severe brain injury but could also have relatively less severe injury with examination confounded by alcohol, residual sedative drugs or a post-ictal state. However, a patient who

has extensor motor responses and one unreactive pupil (E1 V1 M2 P-1) would be more uniformly likely to have a severe brain injury. Indeed, despite a small sample size and missing combinations, a comparison of outcomes of categories equaling a GCS-P score of 3 confirmed the variability in outcome in the first category, and a more dominant poor outcome in the second (Supplemental Table 2).

On balance, we consider the superiority of the GCS-P over the GCS modest, and from a prognostic perspective scoring of GCS and pupillary reactivity separately should be preferred. We further emphasize on a more general note that we would not recommend use of summary scores as replacements for the separate assessment of neurological status using each component of the GCS and PRS in individual patients.[8]

Study strengths and weaknesses

The major strength of this study is its usage of prospectively collected data from 2 large multicenter observational studies across all severities in different continents with standardized data collection, thus ensuring generalizability of findings.

Limitations of our study include the restriction of data collection to North America and Europe, while the majority of TBI worldwide occurs in low- and middle-income countries. Further limitations stem from its observational design with pragmatic data collection. The broad inclusion criteria improve generalizability but potentially result in significant disparities between the CENTER-TBI and TRACK-TBI cohorts.[22-24] CENTER-TBI patients were generally older and suffered more severe TBI compared to TRACK-TBI patients. These factors potentially delineate the apparent differences in mortality and unfavorable outcome between both cohorts. Care should be taken comparing the model performance between the CENTER-TBI and TRACK-TBI models. Discrepancies in case-

mix, however, do not preclude comparative analysis of GCS versus GCS-P or GCS and PRS separately, and may even increase generalizability.

We cannot exclude the possibility that some imputation bias may have occurred. In CENTER-TBI a derived baseline GCS score was used with imputation of missing GCS scores according to IMPACT methodology. In TRACK-TBI the GCS scores were always calculated using the GCS ED admission scores and only imputed if the motor score was available.[14]

Conclusions

GCS-P has a stronger association with outcome after TBI than the GCS alone, and provides a single integrated score. However, this comes at a loss of some information, and for prognostic models, inclusion of GCS and pupillary reactivity as separate scores is preferable to the use of a GCS-P summary score.
