Abstract

Background

Lung adenocarcinoma (LUAD) among never-smokers is a public health burden especially

prevalent in East Asian (EAS) women. Polygenic risk scores (PRSs), which quantify genetic

susceptibility, are promising for stratifying risk, yet have mainly been developed in European

(EUR) populations. We developed and validated single-and multi-ancestry PRSs for LUAD in EAS

never-smokers, using the largest available genome-wide association study (GWAS) dataset.

Methods

We used GWAS summary statistics from both EAS (8,002 cases; 20,782 controls) and EUR (2,058

cases; 5,575 controls) populations, as well as independent EAS individual level data. We

evaluated several PRSs approaches: a single-ancestry PRS using 25 variants that reached

genome-wide significance (PRS-25), a genome-wide Bayesian based approach (LDpred2), and a

multi-ancestry approach that models genetic correlations across ancestries (CT-SLEB). PRS

performance was evaluated based on the association with LUAD and AUC values. We then

estimated the lifetime absolute risk of LUAD (age 30-80) and projected the AUC at different

sample sizes using EAS-derived effect-size distribution and heritability estimates.

Findings

The CT-SLEB PRS showed a strong association with LUAD risk (odds ratio=1.71, 95% confidence

interval (CI): 1.61, 1.82) with an AUC of 0.640 (95% CI: 0.629, 0.653). Individuals in the 95th

percentile of the PRS had an estimated 6.69% lifetime absolute risk of LUAD. Comparison of

LUAD risk between individuals in the highest and lowest 20% PRS quantiles revealed a 3.92-fold

increase. Projection analyses indicated that achieving an AUC of 0.70, which approaches the

maximized prediction potential of the PRS given the estimated genetic variance, would require a

future study encompassing 55,000 EAS LUAD cases with a 1:10 case-control ratio.

Interpretations

Our study underscores the potential of multi-ancestry PRS approaches to enhance LUAD risk

stratification in never-smokers, particularly in EAS populations, and highlights the necessary

scale of future research to uncover the genetic underpinnings of LUAD.

Key Words: Polygenic risk scores, Lung adenocarcinoma, Genome-wide association studies, East

Asian never smokers, Lifetime absolute risk

Introduction

Lung cancer is a major global health challenge, responsible for about 20% of all cancer deaths in 2020[1]. While smoking is the primary etiologic factor, around 25% of lung cancer cases occur in never-smokers, with significant geographical variations[2] . Notably, in East Asia (EAS), never-smoking women exhibit high incidences of lung adenocarcinoma (LUAD), the predominant histologic subtype[3].

Beyond smoking, risk factors for LUAD include environmental and occupational exposures, lifestyle, family history, and genetic susceptibility[4–7]. Genome-wide association studies (GWAS) for never-smoking lung cancer across EAS and European (EUR) populations have identified 28 susceptibility variants at 25 independent loci[8–13]. These GWAS findings enhance our understanding of LUAD's genetic architecture, yet the translation of these findings into clinical practice requires further investigation.

Polygenic risk scores (PRS) aggregate the effects of individual single nucleotide polymorphisms (SNPs) to estimate genetic risk for diseases, playing a crucial role in cancer prevention and screening. Previous efforts primarily utilized EUR populations for lung cancer PRS development[14,15] to better identify high-risk individuals. Nonetheless such PRSs often fall short for EAS never-smokers, reflecting a bias in screening guidelines and the focus of studies on populations with EUR ancestry. Despite ongoing efforts to integrate PRS into clinical practices for complex diseases, as seen in initiatives like the electronic Medical Records and Genomics (eMERGE) network[16], Veterans Affairs Genomic Medicine at Veteran Affairs (GenoVA) study[17], and the Women Informed to Screen Depending On Measures of risk (WISDOM) study[18], lung cancer has been excluded. The predominant global burden of lung cancer, driven primarily by smoking, overlooks the significant impact and potential benefits of PRS in never-smoking populations.

The recent expansion of GWAS across diverse populations, combined with advancements in PRS

methodology, underscores a pivotal shift towards enhancing disease outcome prediction

beyond EUR populations[19]. Notably, the development of multi-ancestry PRS methods marks a

considerable advancement, leveraging data from various ancestral backgrounds to enrich the

predictive accuracy and robustness of PRSs[20–26]. By jointly modeling genetic data from multiple

populations, these approaches improve the predictive power of PRSs, thereby enhancing

disease outcome predictions in non-EUR populations.

While the development and validation of PRSs are critical, the application of an established PRS

in estimating the absolute risk of a disease offers valuable insights into risk stratification,

potentially guiding clinical interventions, such as lung cancer screening. Moreover, projecting

necessary sample sizes for future studies to achieve varying levels of PRS predictive accuracy is

an underexplored area that could significantly impact epidemiological research design and cost-

effectiveness.

This study aims to evaluate the predictive performance of single- and multi-ancestry PRSs for

LUAD in never-smoking EAS individuals using state-of-the-art methodologies. By integrating

multiple datasets, we constructed PRSs based on summary statistics for 5,622 never-smoking

cases and 21,813 never-smoking controls from EAS and EUR ancestries. We assessed the

performance of the PRSs using independent, individual level data of 4,438 never-smoking EAS

cases and 4,544 never-smoking EAS controls. Furthermore, we estimated the lifetime and 10-

year absolute risks of LUAD using the most accurate PRSs developed. Lastly, we projected the

sample sizes needed in future research to achieve specific levels of prediction accuracy with

PRSs in EAS never-smokers (**Figure 1**).

Methods

Study design and data sources

<u>Training data compilation: study population and genotyping</u>

The studies, genotyping protocols, and quality control for PRS construction are previously

described in detail[27]. Briefly, EAS single-ancestry PRSs for LUAD were constructed using

summary data from 3,564 never-smoking LUAD cases and 16,238 never-smoking controls of EAS

ancestry from the Nanjing Lung Cancer Study (NJLCS)[9,28], National Cancer Center of JAPAN

(NCC), and the Research Institute and Aichi Cancer Center (ACC). The NJLCS study combined

data from several cities, genotyped by Affymetrix Genome-Wide Human SNP Array 6.0, as well

as the Oncoarray GWAS[28–30]. The NCC study included lung cancer patients and control data from

multiple Japanese, with genotyping conducted on Illumina HumanOmniExpress and

HumanOmni1-Quad genotyping platforms. Similarly, the ACC study pooled data from the

multiple Japanese medical institutions, and the Nagahama Study, with genotyping performed

using Illumina 610k and Illumina660k platforms. To construct the multi-ancestry PRS, we further

incorporated GWAS summary statistics from 2,058 never-smoking LUAD cases and 5,575 never-

smoking controls of EUR ancestry, genotyped using Illumina Infinium OmniExpress-24 v1.2

BeadChips and Illumina Human660W-Quad BeadChip[13].

<u>Tuning and validation: study population and genotyping</u>

For PRS tuning and validation, we used 4,438 never-smoking LUAD cases and 4,544 never-

smoking controls from the Female Lung Cancer Consortium in Asia (FLCCA)[10,11], an international

consortium composed of never-smoking EAS women from regions including Mainland China,

Singapore, Taiwan, Hong Kong, South Korea and Japan [10,11]. All samples were genotyped using

the Illumina 660W, 370K or 610Q microarrays. The FLCCA data were randomly and equally

divided for tuning (2,219 cases, 2,272 controls) and validation (2,219 cases, 2,272 controls).

Informed consent was obtained from all participants, and the recruitment and data collection

procedures were approved by the local ethics review committees of all participating research

institutes.

Construction of PRS

<u>Single-ancestry PRS methods</u>

PRS-25: We constructed a simple PRS using the 25 independent SNPs (PRS-25) that reached

genome-wide significance (i.e., $P<5\times10^{-8}$) in the largest GWAS for LUAD in EAS population to

date[8]. The PRS-25 was calculated by summing the risk alleles weighed by their effect sizes (i.e.,

per allele log-odds ratio) obtained from a meta-analysis including only never-smokers.

PRS-CT: We generated a PRS using the CT method[31] using PLINK 1.90[32]. This involved the

clumping of SNPs based on LD with a threshold of $r^2=0.1$ within a 500kb window. The LD were

estimated from half of the FLCCA dataset used for tuning dataset. We created nine SNP subsets

by applying incremental P-value thresholds (i.e., $P<5\times10^{-8}$, $P<5\times10^{-7}$,…, $P<5\times10^{-1}$, 1), and

calculated their respective PRSs using PLINK2[32] command "--score cols=+scoresums,-scoreavgs

no-mean-imputation". Using the tuning dataset, the AUC was calculated for each threshold to

identify the most predictive P-value cutoff.

LDpred2-PRS: We applied the LDpred2 method, implemented in the R package bigsnpr[33], using

a Bayesian framework to estimate SNP effect sizes through a shrinkage estimator. This method

leverages GWAS summary statistics, incorporating a prior for effect sizes, while also accounting

for LD across SNPs. Our analysis was constrained to HapMap3 variants, and we calibrated the

model using a range of hyperparameters: the proportion of causal SNPs was set across a 21-

point logarithmic sequence from 10^{-5} to 1 , and the per-SNP heritability was set as a fraction

(0.3, 0.7, 1 or 1.4) of the total heritability estimated by LD score regression[34] divided by the

number of causal SNPs. Lastly, we used the "sparse" option to set weaker effects to zero. The

optimal tuning parameters were selected based on the highest AUC achieved on the tuning

dataset.

PRS-EUR 128: We evaluated the performance of a European-derived PRS (PRS-EUR 128)[35],

which consists of 128 variants obtained from a GWAS of predominately active smokers, on EAS

populations to assess its cross-population applicability.

Multi-ancestry PRSs methods:

LDpred2 PRS + PRS-EUR 128: For the multi-ancestry PRSs, we applied the weighted-PRS

approach by linearly combining the most predictive single-ancestry PRS from the EAS

population (Ldpred2 PRS) with the EUR population-specific PRS (PRS-EUR 128). The weights of

this combined PRS were calculated by applying a logistic regression on the tuning dataset in R

version 4.2.0.

PRS-CSx: We applied PRS-CSx, a multi-ancestry polygenic prediction method that uses a

Bayesian framework with a continuous shrinkage prior to estimate SNP effect sizes from GWAS

summary statistics across different populations[26]. LD reference panels for EUR and EAS,

provided by the PRS-CSx software, were constructed from the 1000 Genomes Project (1KG)

samples [36]. We used the default setting with the gamma-gamma prior hyperparameters (a and

b) at 1 and 0.5, respectively. The shrinkage parameter ϕ was assessed at 10^{-6}, 10^{-4}, 10^{-2}, and 1

within the tuning dataset to select the value with highest AUC. With the optimal ϕ , we

calculated the PRS using posterior effect-sizes from both EAS and EUR populations. Weights

were then estimated to linearly combine the two PRSs on the tuning dataset. The final

performance was then evaluated on an EAS independent validation dataset.

CT-SLEB: We used the recently developed CT-SLEB method to derive a PRS using EAS and EUR

datasets [24]. This method extends the standard CT method by designing a two-dimensional

approach to select SNPs for EAS PRS construction. It incorporates an empirical Bayesian (EB)

framework to model genetic correlations between EAS and EUR. Following this, a super-learning

(SL) model is then applied to integrate multiple PRSs, each generated using distinct p-value

thresholds and clumping parameters[37]. Our implementation of CT-SLEB followed the default

setting with p-value thresholds $p_t = 5\text{x}10^{-8}, 5\text{x}10^{-7}, \dots, 5\text{x}10^{-1}$, or 1, and genetic distances

$d = 50/r^2$ or $100/r^2$, where $r^2 = 0.01, 0.05, 0.1, 0.2, 0.5$ or 0.8. The clumping process for EAS

was based on the LD reference derived from the FLCCA tuning dataset, and the EUR LD

reference was based on the 1KG EUR samples.

Relative and absolute risk calculation for PRSs

To evaluate each PRS's performance, we standardized the scores to a unit standard deviation,

based on the control group in the EAS validation dataset. We then quantified the association

between the standardized PRSs and LUAD risk using the OR and 95% CI, via logistic regression,

adjusting for age and the first 10 principal components (PCs). We evaluated the predictive

performance of the different PRS models through the adjusted AUC values, accounting for age

and top 10 PCs, using the R package RISCA[37]. We further evaluated the ORs of each PRS for risk

of LUAD based on PRS percentiles, setting the middle quantile (40-60%) as the reference

category.

For absolute risk estimates, we used the iCARE software[38] to calculate the cumulative lifetime

(age 30-80) and 10-year absolute risks of LUAD among never-smoking female controls in FLCCA

(N=4,544). Absolute risks were derived by applying the Cox proportional hazard model with the

top performing PRS (CT-SLEB) and age-specific lung cancer incidence and mortality rates in

Taiwan[39].

Projections of CT and LDpred2 PRS performance by sample size

We used GENESIS package [40] to estimate the sample sizes needed for PRS to reach various AUC

levels in the EAS population. This method estimates the expected number of SNP discoveries

and their explained heritability in future studies. Using the GWAS summary statistics from our

EAS training dataset, and the provided LD scores for EAS populations from the 1KG dataset, we

projected the AUC for CT PRS across various case-control ratios, from 1:1 to 1:10, and case

numbers ranging from 5,000 to 200,000. Given GENESIS's specific design for CT PRS, we

developed a extend its application to LDpred2 PRS projections. This involved modeling the

relationship between effective sample sizes with the phenotypic variance ratio between

LDpred2 and CT PRS (**Supplementary Figure 1)**, elaborated in the **Supplementary Note**.

Results

Development and validation of the PRS

We applied several cutting-edge single-and multi-ancestry PRS methods (**Methods,**

Supplementary Figure 2), evaluating their performance in terms of relative risk and AUC within

the EAS validation dataset (**Methods**, **Table 1, Supplementary Figure 2-3)**. Among single-

ancestry PRS methods, the LDpred2 PRS, incorporating 942,591 SNPs, outperformed other

methods, with an odds ratio (OR) per unit standard deviation (SD) of 1.62 (95% confidence

interval (CI): 1.52, 1.73) alongside an adjusted AUC of 0.629 (95% CI: 0.618, 0.641). In contrast,

the PRS designed exclusively for EUR populations underperformed in our EAS population, with

an estimated adjusted AUC of 0.489 (95% CI: 0.477, 0.501), possibly attributed to the inclusion

of smokers in the development of the existing EUR PRS.

Among multi-ancestry PRS methods, the weighted-PRS of EAS and EUR yielded an OR per unit

SD of 1.62 (95% CI: 1.52, 1.72), with PRS-CSx and CT-SLEB showing even stronger association

with ORs of 1.67 (95% CI: 1.57, 1.78) and 1.71 (95% CI: 1.61, 1.82), respectively. Among all the

PRS methods, CT-SLEB had the best performance in the validation dataset with an AUC of 0.640

(95% CI: 0.629, 0.653). Setting individuals in the middle PRS quantile (40th to 60th percentile) as

the reference category, those in the highest 5% of risk for the top performing PRS, CT-SLEB, had

4.17 (95% CI: 3.20, 5.47)-fold risk, whereas those in the lowest 5% had 0.33 (95% CI: 0.21, 0.51)-

fold risk of developing LUAD (**Figure 2**).

Absolute risk of developing lung adenocarcinoma by CT-SLEB PRS

311 Using the iCARE package[38], we estimated the absolute risk of LUAD for never-smoking EAS

312 women, utilizing the CT-SLEB PRS which demonstrated the highest AUC (**Table 1**). The

313 cumulative lifetime risk of LUAD, assessed between age 30-80, varied markedly across PRS

314 percentiles, ranging from a minimal 0.78% in the 5th percentile to a substantial 6.69% in the

315 95th percentile (**Figure 3**). Additionally, the 10-year absolute risk for LUAD in a never-smoking

316 50-year-old woman, a critical age for initiating recommended annual lung cancer screening as

317 per the United States Preventive Services Taskforce (USPSTF), varied from 0.13% in the 5th

318 percentile to 1.11% in the 95th percentile of the PRS distribution, emphasizing the PRS's

319 potential in guiding lung cancer screening strategies.

321 *Projections of polygenic risk score performance by sample size*

323 Using the GENESIS model, we projected the expected AUC of PRS-CT and LDpred2 PRS under

324 varying GWAS sample sizes and case-control ratios for LUAD in never smoking EAS women

325 (**Figure 4**). Our analysis, using the EAS training dataset, estimated approximately 1,772

326 (s.e.=1,641) susceptibility variants that are independently associated with LUAD[27]. This high

327 number of variants underscores the extensive polygenic nature of LUAD, implying relatively

328 small effect sizes for individual SNPs. Based on our current data, the expected AUC for the

329 LDpred2 PRS stands at 0.631 (95% CI: 0.618, 0.641), aligning closely with the actual

330 performance of the LDpred2 PRS in the validation dataset. As our projection increases in sample

331 size to 65,000 cases with a one-to-one case-control ratio and a one-to-ten case-control ratio, the

332 AUC is predicted to rise to 0.681 (95% CI: 0.601, 0.726) and 0.704 (95% CI: 0.629, 0.728),

333 respectively. The upper boundary of our predictions, based solely on PRS, suggests an AUC

334 potential of up to 0.731 (95% CI: 0.640,0.786).

336 *Explaining genetic variance through PRS across different sample sizes*

We also evaluated the genetic variance explained by the PRS under different sample sizes given

the projected results (**Supplementary Note, Table 2**). The current LDpred2 PRS explained 26.6%

of the genome-wide chip heritability, contributing to approximately 16.5% of the 1.84-fold

familial relative risk for lung cancer among EAS never-smokers. Concurrently, genome-wide chip

variants heritability explained 61.9% of the 1.84-fold familial relative risk associated with the

disease. With an expanded sample size of 35,000 cases and 350,000 controls, the constructed

PRS is projected to account for 57.9% of the genome-wide chip variants heritability, and 35.8%

of the 1.84-fold familial relative risk for the disease.

Discussion

We developed and validated single- and multi-ancestry PRSs for LUAD in never-smoking EAS

individuals using the largest GWAS dataset of never-smokers to date. The multi-ancestry PRS

method, CT-SLEB, integrating summary data from EAS and EUR never-smokers, emerged as the

best-performing PRS. It exhibited a dose-response relationship with LUAD risk and achieved

higher AUC than all other evaluated PRSs. Further, our analysis demonstrates the potential of

PRS in stratifying individuals' 10-year and lifetime risk of developing LUAD. Lastly, we projected

the expected discriminatory accuracy of the PRS across a range of sample sizes and case-control

ratios.

To date, GWAS and subsequent PRS models have largely centered on EUR populations [41,42],

rendering them less precise when applied to non-EUR populations and risking the exacerbation

of health disparities [43,44]. Consistent with prior research, our study observed that a lung cancer

PRS constructed using EUR data significantly underperformed when applied to EAS individuals[15].

However, by utilizing novel methods to integrate GWAS data from both EUR and EAS

populations, we demonstrated that a multi-ancestry PRS enhances the precision of risk

stratification for LUAD among EAS never-smokers.

While large-scale efforts to integrate PRS into clinical practice have focused on conditions with

well-established PRS prediction performance[16–18], such as Type 2 Diabetes, breast cancer, and

cardiovascular diseases, lung cancer has been notably absent from these efforts, primarily due

to the overwhelming focus on smoking as a risk factor. This has limited the exploration and

application of PRS in lung cancer risk stratification, particularly among never-smokers. Our study

addresses this gap by presenting a PRS that signifies a 3.92-fold increase in lung cancer risk for

individuals in the top 20% risk quantile, a marked improvement over the 2.09-fold increase

observed in the prior study by Wei et al. [45] for a cohort of Chinese never-smoking women.

The CT-SLEB method's improved performance can be attributed to its ability to utilize diverse

genotyping arrays, thereby including population-specific variants. This aspect, along with the

inclusion of EUR samples in the training set, broadens the genetic diversity and leverages larger

sample sizes for improved model accuracy. Moreover, CT-SLEB excels in modeling genetic

correlations across ancestries, efficiently using both shared and unique genetic markers for

refined disease risk estimations across populations. Lastly, we set up our study with a robust

three-sample split design, dividing datasets into training, tuning, and validation. This ensures

that PRS efficacy is validated independently, effectively reducing the overfitting risk.

Current PRS studies predominantly focus on evaluating relative and absolute risks[8,12,15,45,46], yet

our research introduces a crucial forecast of sample sizes required for differing levels of PRS

accuracy. Our projection analyses indicated that achieving an AUC of 0.70 would approach the

maximized prediction potential of the PRS, given the estimated genetic variance explained by

GWAS chip variants. To reach this level of accuracy, a future study would need to include 65,000

EAS LUAD cases with a 1:4 case-control ratio, or 55,000 cases with a 1:10 case-control ratio.

Notably, accessing large biobanks with publicly available controls could reduce the number of

required cases[47].-These projections offer a strategic framework for planning and designing

future genetic studies on lung cancer, establishing clear benchmarks for PRS model

performance, which is essential for the scientific community in advancing genetic risk

prediction.

Our study has several limitations. First, it focuses on genetic susceptibility without considering

additional questionnaire-based risk factors, aiming primarily to identify the most effective PRS

model within genetic contexts. We plan to conduct integrative analyses that merge PRS with

other risk indicators to refine LUAD risk predictions for never-smokers. Second, our projections

are tailored to single-ancestry PRS models, not fully addressing the intricacies of multi-ancestry

approaches, including diverse sample sizes and genetic correlations across populations. Third,

our validation cohort, derived from the FLCCA and covering various EAS regions, relied on

Taiwanese incidence data for absolute risk estimations. Consequently, our absolute risk findings

may not extend universally to all EAS never-smokers, though our PRS performance assessment

and sample size projections remain applicable to our population of interest. Lastly, the clinical

application of our PRS findings, particularly in screening and risk counseling, is still in

preliminary stages. Despite advancements in using PRS for smoking cessation trials[48], its

implementation for never-smokers in clinical settings has been limited, presenting a significant

area for future research.

In summary, our study evaluates various PRS models to capture the genetic predisposition to

LUAD among never-smoking EAS individuals. It extends beyond risk prediction by estimating

both 10-year and cumulative lifetime absolute risks, and by projecting the sample sizes required

for future GWAS to refine the predictive power of PRSs in future GWAS. Additionally, we

quantify the phenotypic variance captured by PRSs across different sample sizes. Future studies

are crucial to further improve these PRS models, aiming to enhance genetic risk predictions

while integrating a wider array of risk factors. Such efforts will develop more accurate and

comprehensive risk models for LUAD in never-smoking individuals across diverse populations.

(MOST 104-2319-B-400-002). This work was also supported by the Jinan Science Research

Project Foundation (201102051), the National Key Scientific and Technological Project

(2011ZX09307-001-04), the National Natural Science Foundation of China (No.81272293), the

State Key Program of National Natural Science of China (81230067), the National Research

Foundation of Korea (NRF) grant funded by the Korea government (MSIP) (No. NRF-

2014R1A2A2A05003665), Sookmyung Women's University Research Grants, Korea (1-1603-

2048), Agency for Science, Technology and Research (A*STAR), Singapore and the US National

Institute of Health Grant (1U19CA148127-01). The overall GWAS project was supported by the

intramural program of the US National Institutes of Health/National Cancer Institute. The

following is a list of grants by study center: SKLCS (Y.T.K.)—National Research Foundation of

Korea (NRF) grant funded by the Korea government (MEST) (2011-0016106). (J.C.) – This work

was supported by a grant from the National R&D Program for Cancer Control, Ministry of Health

&Welfare, Republic of Korea (grant no. 0720550-2). (J.S.S) – grant number is A010250. WLCS

(T.W.)—National Key Basic Research and Development Program (2011CB503800). SLCS (B.Z.)—

National Nature Science Foundation of China (81102194). Liaoning Provincial Department of

Education (LS2010168). China Medical Board (00726). GDS (Y.L.W.)—Foundation of Guangdong

Science and Technology Department (2006B60101010, 2007A032000002, 2011A030400010).

Guangzhou Science and Information Technology Bureau (2011Y2-00014). Chinese Lung Cancer

Research Foundation, National Natural Science Foundation of China (81101549). Natural

Science Foundation of Guangdong Province (S2011010000792). TLCS (K.C., B.Q)—Program for

Changjiang Scholars and Innovative Research Team in University (PCSIRT), China (IRT1076).

Tianjin Cancer Institute and Hospital. National Foundation for Cancer Research (US). FLCS

(J.C.W., D.R., L.J.)—Ministry of Health (201002007). Ministry of Science and Technology

(2011BAI09B00). National S&T Major Special Project (2011ZX09102-010-01). China National

High-Tech Research and Development Program (2012AA02A517, 2012AA02A518). National

Science Foundation of China (30890034). National Basic Research Program (2012CB944600).

Scientific and Technological Support Plans from Jiangsu Province (BE2010715). NLCS (H.S.)—

China National High-Tech Research and Development Program Grant (2009AA022705). Priority

Academic Program Development of Jiangsu Higher Education Institution. National Key Basic

Research Program Grant (2011CB503805). GEL-S (A.S.)—National Medical Research Council

Singapore grant (NMRC/0897/2004, NMRC/1075/2006). (J.Liu)—Agency for Science, Technology

and Research (A*STAR) of Singapore. GELAC (C.A.H.)—National Research Program on Genomic

Medicine in Taiwan (DOH98-TDG-111-015). National Research Program for Biopharmaceuticals

in Taiwan (DOH 100- TD-PB-111-TM013). National Science Council, Taiwan (NSC 100- 2319-B-

400-001). YLCS (Q.L.)—Supported by the intramural pro- gram of U.S. National Institutes of

Health, National Cancer Institute. SWHS (W.Z., W-H.C., N.R.)—The work was supported by a

grant from the National Institutes of Health (R37 CA70867, UM1 CA182910) and the National

Cancer Institute intramural research program, including NCI Intramural Research Program

contract (N02 CP1101066). JLCS (K.M., T.K.)—Grants-in-Aid from the Ministry of Health, Labor,

and Welfare for Research on Applying Health Technology and for the 3rd-term Comprehensive

10-year Strategy for Cancer Control; by the National Cancer Center Research and Development

Fund; by Grant-in-Aid for Scientific Research on Priority Areas and on Innovative Area from the

Ministry of Education, Science, Sports, Culture and — Technology of Japan. (W.P.)—NCI R01-

CA121210. HKS (J.W.)— General Research Fund of Research Grant Council, Hong Kong

(781511M). The Environment and Genetics in Lung Cancer Etiology (EAGLE), Prostate, Lung,

Colon, Ovary Screening Trial (PLCO), and Alpha-Tocopherol, Beta-Carotene Cancer Prevention

(ATBC) studies were supported by the Intramural Research Program of the National Institutes of

Health, National Cancer Institute (NCI), Division of Cancer Epidemiology and Genetics. ATBC was

also supported by U.S. Public Health Service contracts (N01-CN-45165, N01-RC-45035, and N01-

RC-37004) from the NCI. PLCO was also supported by individual contracts from the NCI to the

University of Colorado Denver (NO1-CN-25514), Georgetown University (NO1-CN-25522), the

Pacific Health Research Institute (NO1-CN-25515), the Henry Ford Health System (NO1-CN-

25512), the University of Minnesota, (NO1-CN- 25513), Washington University (NO1-CN-25516),

the University of Pittsburgh (NO1-CN-25511), the University of Utah (NO1-CN- 25524), the

Marshfield Clinic Research Foundation (NO1-CN- 25518), the University of Alabama at

Birmingham (NO1-CN- 75022), Westat, Inc. (NO1-CN-25476), and the University of California,

Los Angeles (NO1-CN-25404). The Carotene and Retinol Efficacy Trial (CARET) is funded by the

National Cancer Institute, National Institutes of Health through grants U01-CA063673, UM1-

CA167462, and U01-CA167462. The Cancer Prevention Study-II (CPS-II) Nutrition Cohort was

supported by the American Cancer Society. The NIH Genes, Environment and Health Initiative

(GEI) partly funded DNA extraction and statis- tical analyses (HG-06-033-NCI-01 and

RO1HL091172-01), genotyping at the Johns Hopkins University Center for Inherited Disease

Research. This research was supported by the National Research Foundation of Korea (NRF)

grant funded by the Korea government (MSIT) (No. 2020R1A2C4002236)

Female Lung Cancer Consortium in Asia (Tianjin): Tianjin Science and Technology Committee

Foundation, 18YFZCSY00520.

Female Lung Cancer Consortium in Asia (Taiwan): The Ministry of Health and Welfare grants

DOH97-TD-G-111-028 (ISC), DOH98-TD-G-111-017 (ISC), DOH99-TD-G-111-014 (ISC); DOH97-

TD-G-111-026 (CAH), DOH98-TD-G-111-015 (CAH), DOH99-TD-G-111-028 (CAH); National

Health Research Institutes grants NHRI-PH-110-GP-01, NHRI-PH-110-GP-03; and the Ministry of

Science and Technology grants MOST108-2314-B-400-038(CAH), MOST109-2740-B-400-

002(CAH), MOST 111-2740-B-400-002 (CAH), MOST 111-2314-B-400-020 (CAH).

The GWAS of lung cancer in European never smokers was supported by NIH R01 CA149462

(OYG).

OncoArray study in Europeans: The OncoArray data and analysis from INTEGRAL-ILCCO were

supported by NIH U19 CA203654, and U19 CA148127. The data harmonization for ILCCO was

supported by Canadian Institute for Health Research (CIHR) Canada Research Chair to R.J.H, and

CIHR FDN 167273).

European never-smoking lung cancer study: CIA is a Research Scholar of the Cancer Prevention

Institute of Texas (CPRIT) and supported by CPRIT grant RR170048.

Taiwan eQTL study: This study was supported by the Ministry of Health and Welfare grants

DOH97-TD-G-111-028 (ISC), DOH98-TD-G-111-017 (ISC), DOH99-TD-G-111-014 (ISC); DOH97-

TD-G-111-026 (CAH), DOH98-TD-G-111-015 (CAH), DOH99-TD-G-111-028 (CAH); National

Health Research Institutes grants NHRI-PH-110-GP-01, NHRI-PH-110-GP-03; and the Ministry of

Table 1. Prediction performance of different methods for generating polygenic risk scores for lung cancer in never-smoking East Asian populations.

Model type	Number of SNPs	OR (95% CI)[1]	AUC (95% CI)[2]
Single-ancestry method[3]			
PRS-25[4]	25 (24 available)	1.53 (1.44, 1.63)	0.621 (0.612, 0.637)
PRS-CT	8	1.37 (1.29, 1.46)	0.591 (0.585, 0.609)
LDpred2 PRS	942,591	1.62 (1.52, 1.73))	0.629 (0.618, 0.641)
PRS-EUR 128[5]	128 (109 available)	0.97 (0.91, 1.03)	0.489 (0.477, 0.501)
Multi-ancestry method[6]			
LDpred2 PRS + PRS-EUR 128	942,700	1.62 (1.52, 1.72)	0.629 (0.617, 0.640)
PRS-CSx	969,720	1.67 (1.57, 1.78)	0.637 (0.625, 0.647)
CT-SLEB	2,127,229	1.71 (1.61, 1.82)	0.640 (0.629, 0.653)

Abbreviations: SNP, single nucleotide polymorphism; OR, odds ratio; CI, confidence interval; AUC, area under the curve; PC, principle component; CT, clumping and thresholding

[1]ORs are provided per one unit standard deviation of PRS.

[2]Adjusted for age (continuous) and first 10 principal components.

[3]Sample size for single-ancestry PRS methods included 3,564 cases and 16,238 controls of East Asian (EAS) ancestry for training, 2,219 cases and 2,272 controls of EAS ancestry for tuning and 2,219 cases and 2,272 controls of EAS ancestry for validation.

[4]SNPs that reached genome-wide significance in Shi et al., 2023.

[5]SNPs obtained from genome-wide association study conducted in individuals with European ancestry (Hung et al., 2021, Cancer Res.).

[6]Sample size for multi-ancestry PRS methods included 3,564 cases and 16,238 controls of East Asian (EAS) ancestry, as well as 2,058 cases and 5,575 controls of European ancestry for training, 2,219 cases and 2,272 controls of EAS ancestry for tuning and 2,219 cases and 2,272 controls of EAS ancestry for validation.

Table 2. Genetic variance in East Asian lung cancer among never smokers explained by LDpred2 PRS

Sample size[1]	Genetic variance of PRS[2]	Proportion of all-GWAS variants genetic variance explained by PRS[3]	Proportion of Familial risk explained by PRS[4]
Current	0.201	26.6%	16.5%
35,000 cases	0.437	57.9%	35.8%
55,000 cases	0.540	71.5%	44.3%

[1] *Sample Size*: The current sample comprises 3,564 cases and 16,238 controls. Future projections assume a 1:10 case-control ratio for sample sizes of 35,000 and 55,000 cases. Genetic variance projections for the LDpred2 PRS are based on the GENESIS method, originally designed for the CT method (refer to Nat. Genet. 50, 1318-1326 (2018)), extended to include LDpred2 by modeling the variance ratio between LDpred2 and CT (**Supplementary Note**).

[2] *Genetic Variance of PRS*: This corresponds to the heritability on the frailty scale, assuming a polygenic log-additive model underpins this relationship. It quantifies the proportion of the phenotype variation that can be attributed to genetic factors in the context of PRS.

[3] *Proportion of Genetic Variance from All-GWAS Variants Explained by PRS*: This represents the variance of all genome-wide imputable variants as established through LD-score regression (refer to Nat. Genet. 47, 291-5 (2015) and Nat. Genet. 47, 1236-41 (2015)). On the frailty scale, the genetic variance of all GWAS variants is calculated as $\sigma_{GWAS}^2 = Var(\sum_{m=1}^{M} \beta_m G_m)$, where G_m is the standardized genotype for the mth SNP, β_m is the true log odds ratio for the mth SNP and M is the total number of causal SNPs among the GWAS variants. For East Asian never smokers, the estimated genetic variance of all GWAS variants is 0.755.

[4] Proportion of Familial Risk Explained by PRS: This calculates the familial risk in terms of genetic variance using the formula $\lambda_s^2 = \exp(\sigma^2)$, where λ_s is the familial risk when a first-order sibling has the disease, and σ^2 is the genetic variance on frailty-scale. Further details of this calculation can be found in Nat. Genet. 31, 33-36 (2002). For lung cancer in East Asian never-smokers, the familial risk is a 1.84-fold increase, and the genetic variance of all GWAS variants, as estimated through LD-score regression, explains 61.9% of this increased familial relative risk.

Figure 1. Overview of data structure, polygenic risk score (PRS) development, validation and application. Summary statistics from East Asian (EAS) genome-wide association studies (GWAS) were used to develop single-ancestry PRS using methods such as a simple PRS constructed using 25 SNPs that have previously reached genome-wide significance (i.e., P<5x10^{-8}) (PRS-25), a PRS using the clumping and thresholding (CT) method (PRS-CT) incorporating 8 SNPs, and a PRS using a genome-wide Bayesian-based approach, LDpred2 (LDpred2 PRS) incorporating close to a

million SNPs. For the multi-ancestry PRS development, we also used summary statistics from

European (EUR) GWAS, applying the PRS-CSx method that leveraged genome-wide association

summary statistics for close to a million SNPs with a Bayesian continuous shrinkage prior to

model SNP effect sizes across populations, as well as CT-SLEB method, which enhances the

standard CT methods with a two-dimensional approach to select SNPS for EAS PRS construction

by incorporating over 2 million SNPs. Tuning and validation of each PRS was conducted in an

independent EAS individual-level data. Relative risk per PRS quantile was calculated as an odds

ratio (OR) with the middle quantile (40th to 60th percentile) set as the reference, and the area

under the receiver operating curve (AUC) was estimated for each PRS. CT-SLEB PRS was used to

estimate 10-year and lifetime cumulative absolute risk, and PRS-CT and PRS-LDpred2 were used

for sample size projection.

A   PRS-25   B   PRS-CT

C   LDpred2 PRS   D   CT-SLEB

Figure 2. Relative risk estimated for quantiles of each polygenic risk score (PRS) and lung

adenocarcinoma in the validation dataset of women with East Asian ancestry, treating the

40ᵗʰ to 60ᵗʰ percentile as the references. Odds ratios of PRS per standard deviation (SD) and

95% confidence intervals are shown for the single-ancestry 25 SNP polygenic risk score, PRS-25

(A), Clumping and thresholding method, PRS-CT (B), Bayesian-based genome-wide approach,

LDpred2 PRS (C), multi-ancestry approach, CT-SLEB (D).

Figure 3. Lifetime cumulative and 10-year absolute risk of developing lung cancer. Lifetime Cumulative (A) 10-year (B) absolute risk of developing lung adenocarcinoma in never-smoking women in East Asia by percentiles of the CT-SLEB polygenic risk score (PRS). Absolute risks were calculated based on Taiwan's age specific incidence and mortality data and using the PRS relative risks estimated as described in the material and methods section.

Data Availability

All data supporting the findings described in this paper are available in the paper and in the Supplementary Information and from the corresponding author or as otherwise indicated upon request. The individual genotype data for the FLCCA data are in dbGaP phs000716.v1.p1 (Genome-Wide Association Study of Lung Cancer Susceptibility in Never-Smoking Women in Asia). For the NCC and ACC studies, please contact Kouya Shiraishi at kshirais@ncc.go.jp or Takashi Kohno at tkkohno@ncc.go.jp for summary statistics. The GWAS data for the European populations contributing to this study are available at dbGap under accession phs000877.v1.p1 (Transdisciplinary Research Into Cancer of the Lung (TRICL), https://www.ncbi.nlm.nih.gov/projects/gap/cgi-bin/study.cgi?study_id=phs000876.v2.p1), phs001273.v3.p2 (Oncoarray Consortium, https://www.ncbi.nlm.nih.gov/projects/gap/cgi-

bin/study.cgi?study_id=phs001273.v3.p2). To gain access to all data in dbGaP cited in this paper, please apply for dbGaP Authorized Access. GWAS data for the European populations contributing to this study are available under accession phs000877.v1.p1 (ILLCO), phs001273.v1.p1 (OncoArray).
