Key Points

Question: What is the association between glucagon-like peptide-1 receptor agonist (GLP-1 RA) use and the risk of pulmonary aspiration or residual gastric contents in fasted patients undergoing anesthesia?

Findings: This systematic review and meta-analysis of 25 observational studies involving 464,552 patients found that preoperative GLP-1 RA exposure was not associated with pulmonary aspiration among patients undergoing surgery despite being associated with an elevated risk of residual gastric contents.

Meaning: Currently there is limited evidence to suggest that patients using GLP-1 RAs are at a heightened risk of pulmonary aspiration, despite presenting more often to surgery with residual gastric contents than those not using GLP-1 RAs.

Abstract

Importance: Glucagon-like peptide-1 receptor agonists (GLP-1 RAs) are known to slow gastric emptying, however the association between GLP-1 RA use and perioperative aspiration risk is not known.

Objective To summarize the evidence on whether GLP-1 RA exposure is associated with (1) pulmonary aspiration in patients undergoing procedures requiring anesthesia or sedation, or (2) increased residual gastric contents among fasted patients.

Data Sources MEDLINE, EMBASE, Web of Science, and Cochrane Central ClinicalTrials.gov and WHO ICTRP registries (updated 21 Oct 2024), and citation tracking of included studies (25 Oct 2024).

Study Selection: Studies assessing perioperative pulmonary aspiration or residual gastric contents among fasted patients who were using any form of GLP-1 RA.

Data extraction and synthesis: Data was extracted independently and in duplicate. Pooled odds ratios (ORs) were estimated for each outcome using random effect meta-analysis. Certainty of the evidence for each outcome was assessed using the Grading of Recommendations Assessment, Development, and Evaluation framework.

Main outcomes measures: Pulmonary aspiration and increased residual gastric contents, a common surrogate for aspiration risk.

Results: Of 7,994 screened studies, 25 observational studies were included in the analysis. In a meta-analysis of 9 studies involving 184,724 individuals and 471 cases of aspiration, GLP-1RA exposure was not associated with pulmonary aspiration (OR, 1.04; 95% CI, 0.87-1.25, low certainty evidence). In a meta-analysis of 16 studies involving 164,330 individuals and 3,742 cases of residual gastric contents, GLP-1RA exposure was positively associated with residual gastric contents despite appropriate fasting (OR, 4.57;

95% CI, 3.30-6.33, very low certainty evidence). In a meta-analysis of 2 studies involving 877 individuals and 105 cases of residual gastric contents, withholding at least one dose of GLP-1 RA prior to a procedure was not associated with a lower odds of residual gastric contents (OR, 0.67; 95% CI, 0.12-3.67, very low certainty evidence).

Conclusion: Patients using GLP-1RAs are at heightened risk of presenting to surgery with residual gastric contents, though the available evidence does not indicate that this translates to an elevated risk of aspiration. Further research is needed to evaluate the risks and benefits of different strategies for managing these medications during the perioperative period.

Introduction

Glucagon-like peptide-1 receptor agonists (GLP-1 RAs) are widely used for management of obesity and type 2 diabetes.[1] GLP-1 RAs are known to slow the rate of postprandial gastric emptying,[2-4] and there have been recent anecdotal accounts of patients who are taking these medications before surgery aspirating or having increased residual gastric contents despite appropriate fasting.[5-14] This has led various professional organizations to acknowledge that patients taking these medications may be at a heightened risk of pulmonary aspiration or regurgitation during the perioperative period.[15-17]

Guidance from the American Society of Anesthesiologists (ASA) released in 2023 recommends withholding one dose of GLP-1 RA prior to a procedure.[16] Other professional bodies have refrained from recommending to withhold these medications before surgery, citing limitations in the available data.[18-20] Previous systematic reviews have examined the risk of aspiration or residual gastric contents among GLP-1 RA users, however they have been limited to patients undergoing endoscopic procedures,[21, 22] or those temporarily exposed to GLP-1 RAs during the perioperative period.[23] To address uncertainty, this systematic review aimed to summarize the available evidence on whether GLP-1 RA exposure is associated with: (1) pulmonary aspiration in patients undergoing procedures requiring anesthesia or sedation, or (2) increased residual gastric contents among fasted patients. This review also aimed to synthesize the evidence on whether withholding GLP-1 RA medications is associated with reductions in the risk of perioperative aspiration or the presence of residual gastric contents in fasted patients.

Methods

We conducted a systematic review and meta-analysis in line with our prespecified protocol (PROSPERO: CRD42024532229) and reported according to the Preferred

Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement[24] and Meta-analyses Of Observational Studies in Epidemiology (MOOSE) reporting guidelines.[25] Deviations and clarifications to the initial protocol are presented in the supplement (eTable 1 in the Supplement). During the review process, discordance between reviewers were resolved through discussion, or via adjudication by an additional reviewer if consensus could not initially be achieved.

Search strategy

We searched MEDLINE, EMBASE, Web of Science, and Cochrane Central on 19 March 2024 and completed an updated search on 21 Oct 2024 (eMethods 1 in the Supplement). The search was limited to studies published from 2005 onwards, as this was the year of the first approval of a GLP1-RA by the Food and Drug Administration. The ClinicalTrials.gov and WHO ICTRP registries were searched on the same date for information on unpublished or ongoing studies. Forward and backwards citation tracking of included studies was last updated on 25 Oct 2024 using an automated online platform that has been described previously.[26]

Selection criteria

Randomized controlled trials and observational studies were eligible for inclusion if they reported on the association between preoperative GLP-1 RA use and risk of: (1) pulmonary aspiration in fasted patients undergoing anesthesia or procedural sedation; or (2) residual gastric contents in fasted patients undergoing procedures requiring anesthesia or procedural sedation or in healthy volunteers that had fasted for at least 6 hours from solid foods and at least 2 hours for clear liquids, in accordance with standard preoperative fasting requirements.[27]

Studies were excluded if fasting duration was not reported, except for studies involving elective procedures where fasting was assumed to be a requirement. We also excluded studies where the GLP1-RA was commenced in the immediate perioperative period (i.e., within 14 days prior to the procedure or outcome measurement). Non-English studies and conference abstracts were not eligible for inclusion. When multiple studies were derived from the same sample, each study was included in the narrative summary though only the study with the lowest risk of bias across all 6 domains was included in pooled estimates. Ongoing or completed study without published results were identified during screening, but not included in the quantitative synthesis. Studies were screened independently and in duplicate (by JE and SR) using the Covidence systematic review software.[28] Reasons for excluded studies were reported and study authors were contacted to provide further information if eligibility was unclear.

Outcome measures

Pulmonary aspiration included both direct measures of perioperative aspiration or postoperative respiratory complications that were directly attributed to aspiration (e.g. aspiration pneumonitis). Other respiratory complications that were not specifically attributed to perioperative aspiration did not meet this outcome definition. Residual gastric content included gastric residue identified via direct visualization during endoscopy of the upper gastrointestinal tract or gastric contents identified via ultrasound. Individual outcome definitions as described by the study authors are presented in the supplement (eTable 2-3 in the Supplement).

Data extraction and preparation

Key study characteristics and outcome data were extracted from each of the included studies, independently and in duplicate (by CS and JE) using a structured data extraction

template. Adjusted odds ratios (OR) were the preferred effect estimates included in the meta-analyses of both outcomes. For estimates relating to aspiration, adjusted measures of relative risk (RR) were treated as adjusted ORs as odds approximates risk for low event rates.[29] When adjusted estimates were not reported, unadjusted ORs were calculated from the reported number of aspiration events in patients with and without GLP-1 RA exposure. For studies with no events in at least one arm, we added a continuity correction value to both arms that was inversely proportional to the sample size of the other study arm.[29, 30] For estimates relating to residual gastric contents, adjusted RRs were not treated as analogous to ORs, as this is a more common outcome. Study authors were contacted to provide adjusted ORs if multivariable analyses were reported alongside other measures of effect (eTable 4 in the Supplement), or these were estimated by the review team when study data were publicly available (eMethods 2 in the Supplement). When adjusted ORs could not be obtained, unadjusted ORs were calculated directly from the reported number of patients with residual gastric contents in exposed and unexposed groups.

Risk of bias

Risk of bias assessment was conducted independently and in duplicate (by CS and JE) for each effect estimate rather than once per study.[31] For studies examining the association between preoperative GLP-1 RA exposure as compared to no exposure and the risk of pulmonary aspiration or residual gastric contents, we used a modified Quality in Prognosis Studies (QUIPS) tool.[32,33] For estimates of the association between withholding at least one dose of their GLP-1 RA and the study outcomes, we used the Risk Of Bias In Non-randomised Studies - of Interventions (ROBINS-I) tool. In line with ROBINS-I recommendations, studies judged to be at critical risk of bias were excluded

from the meta-analyses.[34] For each of the included studies, bias due to confounding was evaluated by consideration of adjustment for important variables, including age, sex, body mass index (BMI), diabetes, ASA-physical status classification system, medications associated with delaying gastric emptying, and comorbidity burden.

Statistical analysis

Effect estimates for pulmonary aspiration and residual gastric contents were pooled separately. Pooled odds ratios and 95% confidence intervals were calculated via random effect meta-analysis using the restricted maximum likelihood (REML) heterogeneity variance estimator. [35, 36] Heterogeneity was assessed by estimating the I^2 statistic. Funnel plots were assessed visually for evidence of small study bias, and the robustness of estimates to worst case publication bias was assessed by conducting meta-analyses including only non-affirmative studies.[37] Overall certainty of the evidence for each pooled estimate was evaluated in line with the GRADE (Grading of Recommendations, Assessment, Development, and Evaluations) non-contextualised approach, which accounts for risk of bias, inconsistency, indirectness, imprecision, and publication bias of the included studies not considering the clinical context.[38] All statistical analyses were performed using the *meta, metafor,* and *PublicationBias* packages in R Statistical Software (Version 4.3.2, R Core Team).[39, 40]

Results

Study Selection and Characteristics

The literature search identified 7,994 study records (Figure 1), from which 25 observational studies involving 464,552 participants were included in the meta-analysis (Table 1). Fourteen studies that were ongoing or completed without published results at

the time of the final search are summarized separately in the online supplement (eTable 5 in the Supplement).

Pulmonary Aspiration

Eleven retrospective studies assessed pulmonary aspiration among 335,186 patients (Table 2). Of these studies, 6 (55%) included patients who underwent esophagogastroduodenoscopy (EGD), 1 (9%) included EGD and/or colonoscopies, 1 (9%) included mixed endoscopic procedures, 1 (9%) included total knee arthroplasty (TKA), and 2 (18%) involved other elective surgeries. Instances of pulmonary aspiration were identified from electronic medical records or administrative claims data (eTable 2 of the Supplement). Three studies examined individuals undergoing similar procedures from the same administrative database. To avoid double counting of individuals,[41] the study with the lowest risk of bias across all 6 domains was included in the meta-analysis. Nine studies were included in the meta-analysis (Figure 2a). These studies examined 184,724 individuals, of which 471 cases of pulmonary aspiration were identified (Table 3). Preoperative exposure to GLP-1 RAs was not associated with pulmonary aspiration (OR, 1.04; 95% CI, 0.87-1.25, I^2=0%) (Figure 2a). Evaluation of indirectness suggested potential concerns due to a large proportion of studies restricted to endoscopic procedures or patients with diabetes (Table 3). Visual inspection of funnel plot asymmetry did not indicate small study effects (eFigure 1 in the Supplement). Sensitivity analysis restricted to non-affirmative studies was not performed due to an absence of affirmative studies. Overall risk of bias was moderate to high (eTable 6 in the Supplement). For most studies, bias was largely attributed to concerns with selection bias or incomplete adjustment for important prespecified confounders (eTable 7 in the Supplement). Overall certainty in the evidence was low (Table 3).

Residual Gastric Contents

Seventeen studies assessed residual contents (Table 2). Of these studies, 12 (71%) included patients who had undergone an EGD procedure, 2 (12%) included EGD and/or colonoscopies, 1 (6%) included other elective surgeries, and 2 (12%) included healthy volunteers. Residual gastric contents were identified via retrospective review of electronic medical records for all 14 studies involving endoscopic procedures, with the remaining 3 studies having measured residual gastric content prospectively using gastric ultrasound (eTable 3 in the Supplement).

Sixteen studies were included in the meta-analysis (Figure 2b). These studies examined 164,330 individuals, of which 3,742 had residual gastric contents (Table 3). Preoperative GLP-1 RA exposure was associated with higher odds of residual gastric contents (OR, 4.57; 95% CI, 3.30-6.33; I^2=60%) (Figure 2b), however this estimate was impacted by moderate to substantial heterogeneity. Although our certainty in evidence was increased due to the large effect, evaluation of indirectness suggested potential concerns due to a large proportion of studies restricted to endoscopic procedures (Table 3). Visual inspection of funnel plot asymmetry indicated that small study effects may have inflated this estimate (eFigure2 in the Supplement), though a sensitivity analysis restricted to non-affirmative studies indicated that our pooled estimate was robust to even worse-case publication bias (OR, 3.29; 95% CI, 1.36-7.95) (eFigure 3-4 in the Supplement). Overall risk of bias was predominantly high (eTable 8 in the Supplement). For most studies, bias was largely attributed to high concerns with study participation, outcome measurement, and incomplete adjustment for important prespecified confounders (eTable 9 in the Supplement). Overall certainty in the evidence was very low (Table 3).

Association Between Time Since Last Dose and Residual Gastric Contents

Three observational studies assessed the association between the time since last dose of GLP-1RA medication and residual gastric contents (Table 2). These studies examined 910 patients who were using GLP-1 RA, of whom 113 had residual gastric contents (eTable 10 in the Supplement). One of these studies examined a cohort using either weekly and daily dosed formulations, and the remaining studies were restricted to cohorts using weekly formulations. One study at critical risk of bias was excluded from the meta-analysis (eTable 11 in the Supplement).

Two studies were included in the meta-analysis (Figure2c). These studies examined 877 individuals and 105 cases of residual gastric contents (Table 3). Withholding at least one dose of GLP-1 RA prior to a procedure was not associated with a lower odds of residual gastric contents (OR, 0.67; 95% CI, 0.12-3.67; I^2=66%). This estimate was impacted by substantial heterogeneity and very wide confidence intervals highlighting imprecision in this estimate (Table 3). Evaluation of indirectness suggested potential concerns due to a limited number of studies and half restricted to EGD procedures. Publication bias was not formally evaluated, as only two studies were included in the meta-analysis. Overall risk of bias across studies analysed was moderate to serious (eTable 11 in the Supplement). Key concerns were attributed to potential bias due to residual confounding and outcome measurement. Overall certainty in the evidence was very low (Table 3). No studies measured the association between the time since last dose of GLP-1 RA and pulmonary aspiration.

Discussion

In this systematic review and meta-analysis, we assessed data from 25 observational studies involving 464,552 participants to evaluate the relationship between GLP-1 RA use and risk of perioperative aspiration among patients undergoing elective procedures. Our

findings indicate that patients using GLP-1 RAs prior to an elective procedure are at a higher risk of presenting with residual gastric contents compared to those not using GLP-1 RAs. Despite this, the available evidence does not indicate that preoperative GLP-1 RA use is associated with risk of perioperative aspiration, and the relationship between withholding GLP-1 RAs before surgery and aspiration risk remains unstudied. Pooled estimates from a small number of studies indicate that withholding at least one dose of their GLP-1 RA before surgery does not significantly lower the risk of presenting with residual gastric contents, when compared to maintaining a regular dosing schedule. However, the potential influence of residual confounding across included studies and imprecision in this estimate substantially weakens our certainty in these findings.

These findings may provide some degree of reassurance to both patients and clinicians about the risk of aspiration among patients using GLP-1 RAs prior to elective procedures. However, some caution is warranted, given low to very low certainty in the available evidence. High rates of residual gastric contents among these patients may be a cause for concern, independent of any assumed association with aspiration risk. Gastric residue may complicate procedures that require clear stomach visualization, such as gastroscopy, potentially leading to aborted procedures due to inadequate gastric clearance. Aborted procedures expose patients to unnecessary anesthetic risks while also adversely affecting the efficient of healthcare resources.[42] Consequently, these findings indicate that tailored guidance on the perioperative management of GLP-1 RAs may be warranted for procedures reliant on an empty stomach even in the absence of heightened aspiration risk.

Consensus-based guidance from the ASA currently recommends holding at least one GLP-1 RA dose prior to an elective procedure,[16] while other professional bodies have

refrained from endorsing similar recommendations.[18-20] This review identified no direct evidence to support the assumption that holding GLP-1 RA medications is associated with a lower risk of aspiration and there is very low certainty evidence that withholding at least one dose of GLP-1 RA prior to a procedure is not associated with a lower odd of residual gastric contents. Importantly, available studies did not examine the potential risks of withholding these medications, such as glycaemic instability or abrupt increases in blood pressure.[43] Given the absence of evidence relating to such risks and the small absolute risk of aspiration following appropriate fasting, it remains unclear if routinely withholding GLP-1 RA medications is warranted prior to elective procedures.

This review highlights the need for targeted research exploring the risks and benefits of strategies for managing GLP-1 RA medications prior to elective procedures. While several ongoing observational studies were identified in this review, it is unclear whether their findings will add to the current evidence in a way that alters clinical practice. Importantly, only one randomized controlled trial on the effect of withholding GLP-1 RAs on aspiration and increased residual gastric content risk was identified by our search of ongoing studies. Such trials are urgently needed to assess the efficacy and safety of holding these medications prior to surgery, and of alternative strategies such as using daily-dosed GLP-1 RAs as bridging therapies prior to surgery,[44] routinely using prokinetic agents,[45] or altering fasting protocols for patients using these medications.[46] A rapid update to this review will be warranted once data is available from randomized controlled trials, as such evidence will be critical to informing recommendations presented in future clinical practice guidelines.

Limitations

The findings of this review should be interpreted within the context of several limitations. First, there was heterogeneity in how outcomes were described across the included studies. This included differences in measurement methods, such as using endoscopy versus gastric ultrasound to assess gastric contents, and differences in outcome definitions, such as distinguishing between pulmonary aspiration and aspiration pneumonitis. Second, the available evidence is drawn largely from populations undergoing upper endoscopies, a procedure that is unique insofar as it allows for intraoperative management to be altered following direct visualization of residual gastric contents. This may limit the applicability of our findings to patients undergoing most types of elective procedures. Third, an absence of studies with a pre-registered protocol raises concerns about potential selective analysis and reporting, though the findings appeared to be largely robust to publication bias. Fourth, none of the studies were judged to be a low risk of bias, which is reflected in the overall certainty of the evidence being low to very low. Finally, we excluded two potentially eligible studies that were not published in English.[47, 48] It is unclear if this exclusion is likely to have altered our findings.

Conclusion

This systematic review and meta-analysis found that patients using GLP-1 RAs are at a heightened risk of presenting for surgery with residual gastric contents, though this does not necessarily indicate an increased risk of aspiration. The available evidence to support withholding GLP-1 RAs before surgery is derived from a small number of observational studies and is impacted by a high degree of uncertainty. Given the uncertainty of evidence and absence of randomized controlled trials, ongoing research is needed to evaluate the risks and benefits of different strategies for managing these medications during the perioperative period.

Yes	0	3 (18 %)
No	11 (100 %)	14 (82 %)

Percentages may not sum to exactly 100 due to rounding.
Abbreviations: EGD, esophagogastroduodenoscopy; GLP-1 RA, glucagon-like peptide-1 receptor agonist; TKA, total knee arthroplasty.

Table 3. Summary of findings and GRADE assessment

Outcome	No. of patients (studies)	Event rate control	Event rate exposure	Relative effects (95% CI)	Absolute Risk difference (95%CI)	Risk of bias	Inconsistency	Indirectness	Imprecision	Publication bias	Large effects	Certainty of Evidence
Pulmonary aspiration[a]	184724 (9)	0.20% (218/110830)	0.34% (253/73894)	OR 1.04 (0.87 to 1.25)	1 more per 10,000 (2 fewer to 5 more)	Serious[f]	Not serious	Serious[k]	Not serious	Not serious	No upgrade	Low
Residual gastric contents[a]	164330 (16)[c]	2.1% (3358/159845)	9.1% (384/4236)	OR 4.57 (3.30 to 6.33)	68 more per 1,000 (44 more to 101 more)	Very serious[g]	Serious[i]	Serious[l]	Not serious	Not serious	Upgrade[o]	Very Low
Time since last dose[b]	877 (2)	17.7% (82/464)[d]	5.6% (23/413)[e]	OR 0.67 (0.12 to 3.67)	5 fewer per 100 (15 fewer to 26 more)	Very serious[h]	Serious[j]	Serious[m]	Very serious[n]	Not serious	No upgrade	Very Low

Not serious indicates that no reason was found, or the reason was not important enough to warrant downgrading the evidence; Serious indicates that the evidence is downgraded by one level; Very serious indicates that the evidence is downgraded by two levels; Upgrade indicates that the certainty of the evidence is increased by one level.

[a] In line with GRADE recommendations for assessment of evidence about prognostic factors, we started with a high certainty in the evidence.[38]

[b] In line with GRADE recommendations for outcomes assessed with the ROBINS-I tool, we started with high certainty of evidence.[74]

[c] One study did not report event rates for patients using GLP-1 RAs, therefore total number of patients is greater than the sum of control and exposure groups

[d] Control group involves patient who did not hold their GLP-1 RA prior to procedure

[e] Exposure group involves patients who held their GLP-1 RA for at least one dose prior to procedure

[f] Overall bias was moderate or high across included studies. Studies at high risk of bias did not meaningfully impact the pooled estimate. Concerns with incomplete or missing adjustment of confounders, potential selection bias, and inadequate details regarding outcome measurement.

[g] Overall bias was predominantly high across included studies. Concerns with incomplete or missing adjustment of confounders, potential selection bias, and inadequate details regarding outcome measurement.

[h] Overall bias was moderate to serious across included studies. Concerns with potential confounding and inadequate details regarding outcome measurement.

[i] Downgraded because of moderate to substantial heterogeneity (I2=60%).

[j] Downgraded because of substantial heterogeneity (I2=66%).

[k] Downgraded because 6/9 limited to endoscopic procedures and 4/9 limited to patients with diabetes.

[l] Downgraded because 13/16 limited to endoscopic procedures.

[m] Limited number of studies. Half limited to upper endoscopy procedures.

[n] Downloaded because of very wide confidence intervals.

[o] Certainty of evidence is increased by one level because the relative point estimate and confidence intervals are >2.
