ABSTRACT

Background: Psychiatric disorders are notoriously heterogenous, often rendering diagnostic efforts challenging, and leading to poor therapeutic outcomes. The growing emphasis on 'transdiagnostic' approaches in psychiatry aligns well with the National Institute of Health-devised Research Domain Criteria (RDoc) framework that seeks to enable precision psychiatry. Here, we sought to identify transdiagnostic subgroups, which share behavioral and neural abnormalities, in a large population of psychiatric inpatients treated at a tertiary psychiatric hospital.

Methods: The sample included 1,571 patients across five units within the Depression & Anxiety Disorders Division at McLean Hospital who completed self-assessments as part of an ongoing quality-of-care improvement project. Self-assessments included validated measures of depression, anxiety, anhedonia, trauma, personality and substance misuse as well as broader screening questions. First, we identified naturally occurring transdiagnostic subgroups based on the self-reported questionnaires using consensus clustering to implement partition-around-medoids. In a subsample, we ascertained brain functional connectivity differences between the resultant subgroups using a multi-granular approach, i.e. whole-brain to connection-wise.

Results: In a k=2 partitioning solution, the first transdiagnostic cluster; C1 (N=809) had consistently higher means across all questionnaires compared to the second cluster; C2 (N=762). QIDS total score (P<0.0001, effect size = 0.54) and BASIS-24 derived total score (P<0.0001, effect size = 0.53) showed the largest difference between the groups. In follow-up imaging analysis (N=26) functional connectivity (FC) differences were observed connection-wise (P<0.0001) and between functional networks (P<0.0001), with C1 showing stronger FC than C2. Cluster-by-sex analyses revealed that females had higher BASIS-24 derived depression/functioning (C1|C2; P<0.0001 | P<0.0001), and QIDS (C1|C2; P<0.0001 | P<0.0001) scores compared to males. This was coupled with greater intermodular FC in males than females in C1 (P<0.0001) and C2 (P<0.0005).

Conclusions: These results suggest that inpatients with transdiagnostic symptoms show biobehavioral abnormalities, underpinned by sex differences. Behaviorally, this is a function of acuity, i.e., severity of psychopathological symptoms, and not diagnosis. Biologically, the dysfunction captured here may span across various brain networks, rather than a singular region.

INTRODUCTION

Psychiatric diagnostics beyond the DSM

Classification of mental health disorders is traditionally represented by the Internal Classification of Disease (ICD) or Diagnostic & Statistical Manual of Mental Disorders (DSM), where often dichotomous categorical diagnoses are made following evaluation of a series of clinical symptoms. While nosology is needed for a variety of purposes in clinical medicine, since its inception and continual instrumentalization, psychiatric taxonomy has been a persistent subject of contention (1). A key issue pertains to comorbidity, including (i) symptom comorbidity - symptom arrays across different diagnoses may overlap, and conversely, different symptom patterns can result in the same diagnosis, and (ii) psychiatric comorbidity – co-occurrence of mental health disorders in an individual at a given time (1, 2). This ultimately leads to heterogeneity in clinical manifestations, disease trajectories, and treatment (3). Another problem with a categorical approach to psychopathological diagnosis is that of subsyndromal or subthreshold symptoms (4). Symptoms of a disorder usually present at a variety of levels of severity. However, if symptoms fall below a diagnostic threshold, diagnosis may be made without accounting for these symptoms, whose treatment could alleviate dysfunction and improve clinical condition. Is there an approach then, to implement data-driven psychiatric diagnostics in place of the ICD/DSM?

Transdiagnostic paradox in psychiatry: the 'common factor' vs 'subtypes'

There is mounting support for a transdiagnostic approach in psychiatry (5), which cuts across existing traditional diagnostic boundaries or, more radically, sets them aside altogether, to provide novel insights into mental health difficulties. Evidence for this concept is the general psychopathology (p) factor (6) that is purported to capture latent 'shared variation' in behavioral symptomatology of internalizing (e.g. MDD, GAD), externalizing (e.g. ADHD, conduct disorder) and thought (e.g. schizophrenia, bipolar) disorders. Although 'p' remains elusive, prior hypotheses regarding key sources of latent shared variability include not only general psychopathology, as framed by the original authors (7), but also phenotypic factors such as psychosocial risk factors (8). A growing number of studies are also beginning to explore analogous factors for to identify transdiagnostic biomarkers in psychiatry (9), such as genetic/heritable components (10, 11) and neural substrates (12, 13).To an extent, this line of thinking also complements the emerging 'subtyping' investigations in psychiatry seeking to identify nuances within a single disorder and - more relevant here - across multiple disorders, via clustering methods (14, 15). The rationale is

that resulting 'subtypes' or 'subgroups' might reveal latent properties distinguishing the subgroups as opposed to latent feature(s) that are more common, i.e., a transdiagnostic 'p' factor (also known as 'common factor'). Furthermore, biology-based subtypes may be more specifically targeted by differential treatments than current diagnostic definitions.

Current investigation

Perhaps most critically, this transdiagnostic thinking has helped to inspire the creation of the Research Domain Criteria (RDoC) framework, which attempts to base psychiatric nosology on neuroscience and behavioural science, rather than DSM-defined diagnostic categories, all in an effort towards a more precise, personalized psychiatry (16, 17). In light of this, the present study aims to concurrently examine biobehavioral differences as well as similarities in transdiagnostic subgroups, specifically in an acute inpatient psychiatric setting. This was instrumentalized via (i) clustering of mental health and lifestyle instruments in a population of patients receiving psychiatric hospital level-of-care, and subsequently (ii) examining brain functional connectivity properties in resultant subgroups (**Figure 1**). Previous transdiagnostic clustering studies support the existence of diagnostically mixed subtypes across two or more disorders (18, 19). To our knowledge, Pelin et al. (2021) (19) constitutes the largest ($N_{discovery}$=1,250) published transdiagnostic subtyping study. Here we expand on this with a larger sample size with likely more acute levels of symptoms. We hypothesized that resultant patient clusters or transdiagnostic subtypes would principally be discriminated by variations in severity of mental health symptoms, akin to majority of findings in single-disorder subtyping studies (20) . We further hypothesized that the clinically-derived clusters would show related differences in brain functional connectivity.

METHODS & MATERIALS

Study design and Participants

Participants of the investigation were patients across five units of the Division of Depression & Anxiety Disorders at McLean Hospital. All procedures were approved by the Mass General Brigham Institutional Review Board (IRB), and all participants provided written informed consent. Between January 2018 and November 2023, research assistants approached patients and administered computer-based questionnaires (see Methods: Self-reported symptom scales) within 48 hours of admission as part of the Clinical Measurement Initiative (CMI; IRB# 2021P002444) (21), an ongoing patient care quality improvement/quality control (QI/QC) project. The self-assessments were administered on Apple iPads using Research Electronic Database Capture, *REDCap*. There were few exclusion criteria: high acuity preventing involvement, cognitive deficits limiting comprehension, and language barrier preventing communication.

Figure 1: Study design and analyses overview. Part 1 of the study focused on unsupervised learning, that is, clustering of behavioral instruments ascertaining mental health symptoms and substance use. Part 2 of the investigation focused on examining brain-wide functional connectivity (FC) differences between resultant transdiagnostic subtypes. This was implemented through a multi-granular approach i.e., beginning with whole-brain global FC, intermodular FC (between functional networks) and intramodular FC (within functional networks), nodal or region-wise FC, and finally edge- or connection-wise FC.

Self-reported symptom scales

All participants completed the following self-report standardized instruments assessing psychological and mental health symptoms (see Supplementary Materials Section S2): 24-item Behavior and Symptom Identification Scale (BASIS-24) (22), Quick Inventory of Depression Severity Scale (QIDS) (23), 7-item Generalized Anxiety Disorder (GAD-7) (24), Snaith-Hamilton Anhedonia Pleasure Scale (SHAPS) (25), PTSD checklist for DSM-V (PCL-5) (26), and the McLean Screening Instrument for Borderline Personality Disorder (MSI-BPD) (27). Participants also completed a series of questionnaires assessing substance use: Heaviness of Smoking Index (HSI; tobacco consumption) (28), concise version of the Alcohol Use Disorder Identification Test (AUDIT-C; alcohol consumption) (29), and the Drug Abuse Screening Test (DAST-10; drug use) (30). These questionnaires were completed after admission (i.e., within 48 hours). Participants completing the questionnaires beyond the indicated time frame were excluded. Clinical and sociodemographic information e.g. age, sex, personal information e.g. educational background, and family history were also collected as part of self-reported assessment. BASIS-24, QIDS, and GAD-7 drawn at discharge were used for validation.

Consensus clustering

To identify naturally occurring transdiagnostic subgroups based on self-reported psychopathological symptoms and lifestyle habits, we performed consensus clustering (31) implemented via the *ConsensusClusterPlus* (v1.66.0) software (32) in R (v4.0.2). Consensus clustering improves robustness of clustering solution(s) by running multiple iterations of a given clustering algorithm through subsampling and evaluating stability of clustering assignments for each observation. The algorithm we implemented with consensus clustering was partitions around medoids (PAM). PAM, a *k*-medoids based algorithm, is a partitioning technique akin to the more commonly used *k*-means. However, where k-means solves the partitioning problem with respect to centroids (cluster means), PAM does so with respect to medoids (cluster centers being members of the cluster) that minimize distances or dissimilarities to all other observations within a cluster. The minimize error, PAM iterates over each cluster constituent as a medoid.

We used a subsampling parameter of 80% with 1000 iterations. The number of possible clusters (*k*) was selected to range from 2 to 10 to avoid excessive numbers of clusters that would not be meaningful. The ideal number of clusters were ascertained by evaluating the consensus matrix heatmap that visualize within-cluster (*k*) consensus score, and cumulative

distribution function (CDF). The within-cluster consensus score (range; 0-1) is defined as the mean consensus value for all pairs of individuals belonging to the same cluster across iterations, i.e., at each iteration, if an individual or observation is assigned to the identical as previous iteration, value of 1 is ascribed, otherwise 0. We applied a strict threshold in defining ambiguous clustering, that is, a consensus score greater than 0 or less than 1 (as opposed to a more lenient boundaries e.g., 0.1 vs 0.9) was considered ambiguously clustered. A final value of 1 indicates strongest cluster stability.

Partial least squares – discriminant analysis

To examine feature importance in cluster assignment, we performed partial least squares – discriminant analysis (PLS-DA), a supervised machine learning technique that is commonly used in multivariate analysis for dimensionality reduction, classification and feature selection (33). PLS-DA could be conceptualized as a 'supervised' version of Principal Component Analysis (PCA) and a categorical version of PLS-regression, in that it performs dimensionality reduction through linear transformation, but with full awareness of the class labels. It ascertains a linear relationship between two input matrices i.e., qualitative response variable or Y-variate (in our case, resulting cluster labels for each participant), and a set of continuous predictors or X-variate (in our study, 15 questionnaire-derived variables used in clustering analysis). Next, PLS-DA constructs a set of orthogonal components (akin to PCA components) that maximize the sample covariance between the response (Y) and the linear combination of the predictor variables (X). We implemented PLS-DA through *mixOmics* v6.26.0, in R v4.0.2 (34) with $k=2$ number of components, maximum 1000 number of iterations until convergence, convergence value *tol=1e-06*, and normalization applied to X matrix (scale parameter set to true; each data column is transformed to zero mean and unit variance). No parameter tuning, or cross-validation was performed as PLS-DA was purely implemented in our analyses to examine feature importance in clustering, and not for classifier training purposes.

Resting-state functional MRI acquisition and preprocessing

A subset of CMI participants were also enrolled in the Psychometrics in McLean (IRB# 2016P001255) study that began collected MRI data following an amendment to the IRB, dated 05/17/2022. Data for Part 2 of our analysis were drawn from the Psychometrics at McLean MRI collection. Resting-state fMRI (rs-fMRI) data were acquired on a 3.0T Siemens

Magnetom Prisma (Erlangen, Germany) scanner using multi-echo (ME) echoplanar imaging (EPI) sequence with: relaxation time (TR) = 1.33s; echo times (TE1, 2, 3, 4) = 13ms, 29ms, 48ms and 62ms; flip angle = 67 degrees; acquisition time = 7mins 40s = 300 volumes in each fMRI time series. ME-EPI data were collected as 60 slices (transversal) at 0 degrees to the A–P line with field of view = 216mm, for voxel resolution of 2.5 × 2.5 × 2.5mm. The first three volumes were discarded (dummy scans) and the remaining data were preprocessed. Standard preprocessing was performed using *fMRIPrep* (v23.0.2) with default parameters (35). As part of denoising, a 3mm FWHM kernel was applied for smoothing, and 24 nuisance parameters were regressed out (24 regressors; 6 motion derivatives (3 rotation and 3 translation), white Matter, CSF, and the respective first and second-order derivatives). Volume-to-surface mapping was then performed on the preprocessed and cleaned data. rs-fMRI data (volumetric standard space; MNI152NLin6Asym) were registered to standard space (surface; fsaverage HCP-MMP 1.0). Timeseries were extracted across 180 bilateral cortical regions (36) and 5 subcortical region-of-interests (ROIs) (FSL Harvard-Oxford atlas; accumbens, caudate, putamen, amygdala, hippocampus), resulting in 370 ROIs in total.

Functional connectivity matrix construction and multi-granular connectome decomposition

FSLNets (https://fsl.fmrib.ox.ac.uk/fsl/fslwiki/FSLNets) was implemented via MATLAB to generate 370 x 370 symmetric connectivity matrices for each participant using the resultant timeseries. Full pair-wise correlations (normalized covariance) with Fisher r-to-Z transformation were estimated using the nets *nets_mats* function ('corr'). Participants with high degree of head motion estimated by framewise displacement (FDrms > 0.3mm), were excluded (N = 5) (**Figure S2**). To gain more functional resolution of connectivity matrices, each ROI was also assigned to one of the 7 functional modules i.e. visual (V), somatomotor (SM), dorsal attention (DA), ventral attention (VA), limbic (L), frontoparietal control (FP), and default mode network (DMN), as described in Yeo et al. (2011), based on its co-localisation with these canonical resting-state networks. The remaining 10 subcortical regions were assigned to a subcortical (SC) module. Details of functional node-labelling schemes are further described in previous publications (37, 38). For statistical comparison, whole brain FC was decomposed using a multi-granular approach i.e., beginning with global FC, intermodular FC (between Yeo functional networks) and intramodular FC (within Yeo functional networks), nodal or region-wise FC (i.e., per ROI), and finally edge- or connection-wise FC **(Figure 1)**.

Statistical methods

Correlation between clustering predictors were estimated using Spearman's rank correlation. Between-group comparison to ascertain cluster differences were estimated using non-parametric Kruskal-Wallis test. Effect size reported were Cohen's d estimated from η^2 (eta squared) using the formula $d = 2 * \sqrt{\eta^2} / \sqrt{1 - \eta^2}$ (39). η^2 was initially derived from Kruskal-Wallis H-test using the formula $\eta^2 = (H - k + 1)/(n - k)$ where *k* = number of groups, and *n* = number of observations. In Part 2, between-group comparison of brain FC were estimated using two-sample Kolmogorov-Smirnov tests and T-tests. P-values were adjusted for multiple comparisons with 5% false discovery rate (FDR; α =0.05). Post hoc estimation of interaction effect between factors was performed via two-way (2x2) ANOVA was performed. All statistical tests were performed in R (v4.0.2).

RESULTS

Sample characteristics

After quality control, N=1,571 participants remained for initial analyses (**Table 1**). The cohort was sex-balanced (46% 'Male'), with a wide age range (18 – 81 years). Psychological instruments (BASIS-24, QIDS, SHAPS, GAD-7, PCL-5, MSI-BPD) were more strongly positively correlated with each other (ρ range: -0.077 – 0.815) than with demographic variables (ρ range: -0.198 – 0.169) and substance use instruments (ρ range: -0.167 – 0.516) (**Figure 2A**). There were significant negative correlations between demographic factors and symptom scales, including BASIS-24 derived depression functioning subscale (sex; P = 2.28e-15, ρ = -0.199), and total scores for QIDS (sex; P = 3.76e-14, ρ = -0.194) and MSI-BPD (age; P = 2.56e-14, ρ = -0.192). The correlation structure was retained under PTSD (PCL-5 total score) and sex-partialized correlation matrices. PTSD-adjustment resulted in weaker positive correlations (ρ range: -0.223 – 0.715) across all instruments, as well as the emergence of weak negative correlations between anhedonia (SHAPS) and substance use particularly (ρ range: -0.157 — -0.113), suggesting the influence of PTSD/trauma experience in substance abuse in the context of anhedonia (**Figure S3A**). In contrast, sex-adjustment enhanced positive associations between psychological instruments (ρ range: -0.184 – 0.807) (**Figure S3B**), and yielded strong positive correlations between age and mental health symptoms (ρ range:0.584 – 0.651) that were not observed prior (**Figure 2A**). Females were significantly younger (**Figure S6A**; µFemale = 31.9year, µMale = 35.5years; P = 4.74e-9) than males in our cohort.

Clustering outcome and optimal partitioning solution

Upon visual and empirical evaluation of consensus matrices (**Figure S4A**) and corresponding cumulative distribution function (CDF) plot (**Figure S4B**), *k=2* was selected as the best partitioning solution. The *k=2* consensus matrix provided the best separation between clusters, with lower proportion of ambiguously clustered pairs (17.96%) across iterations, denser upper diagonal block (18.63%) and sparser off-diagonals compared to *k=3* (ambiguous clustering ['0'] = 22.04%; consistent clustering ['1'] = 2.6%) (**Figure S4A**). Similarly, inspection of CDF plot for *k=2* showed a sharp increase at consensus scores 0 and 1, with an evident horizontal line for intermediate consensus values, suggesting more stable clustering (**Figure S4B**).

Cluster identity

To determine cluster identity, we examined differences in demographic factors, psychological and lifestyle indices between resultant clusters (cluster 1; C1 (N=809), cluster 2; C2 (N=762)). Both clusters showed significant differences across all input variables (Table S1). C1 had consistently higher mean values, in particular for QIDS total score (P<0.0001, Cohen's d = 0.54), BASIS- 24 total score (P<0.0001, Cohen's d = 0.53), and BASIS-24 derived depression/functioning (P<0.0001, Cohen's d = 0.52) compared to C2. Anxiety (GAD-7 total) (GAD-7 total score; P<0.0001, Cohen's d = 0.42) and anhedonia (SHAPS total) were also significantly higher in C1 compared to C2 (P<0.0001, Cohen's d = 0.31), although the effect sizes were smaller than questionnaires weighing on multiple psychopathologies. Substance use (drugs, alcohol and tobacco) was also significantly higher in C1 compared C2, although effect sizes were more minimal (P- values = P<0.0001 [DAST-10], 0.013 [AUDIT-C], 0.044 [HSI]; Cohen's d range: 0.008 – 0.04) when contrasted against psychopathologies. Sex and age differed between C1 and C2, although only sex was significant. There were a greater proportion of females in C1 than in C2 (C1|C2; $N_{females}$ = 59.9% | 49.4%; P = 2.768e-05). This resulted in a higher mean age for C2 than C1, as proportion of males were marginally higher in the former (C1|C2 µAge = 33.0years | 34.2years; P = 0.192). To examine cluster separation, we performed principal component analysis (PCA) on clustering predictors (**Figure 2B-C**). PC1, a weighted average of all predictors was significantly different between the clusters (P<0.0001, t(1494)= -45.752) with C1 loading higher i.e. more negative PC1 (µC1 = -1.67), than C2 (µC2 = 1.77), corroborating our prior observations. PC2 also differed between the clusters, although the effect size was

considerably smaller than PC1 (P<0.0001, t(1522)= 5.973; C1|C2 µPC2 = 0.179 | -0.189), evident from the limited cluster separation across the Y-axis in the biplot (**Figure 2B**).

Validation using identical unobserved questionnaire data drawn at discharge supported the initial observations. Both clusters showed significant differences across all instruments apart from SHAPS (anhedonia), despite the effect sizes being smaller compared to admission-drawn measures (**Table S2**). C1 had consistently higher mean values, particularly for BASIS- 24 total score (P<0.0001, Cohen's d = 0.26), QIDS total score (P<0.0001, Cohen's d = 0.25), and anxiety (GAD-7 total score; P<0.0001, Cohens'd = 0.53) compared to C2.

Figure 2: Association structure between clustering variables and clustering solution (*k*=2) and phenotypic predictors of transdiagnostic subgroups. (A) Behavioral instruments ascertaining mental health symptoms were generally more strongly correlated with each other, noted by the highly correlated (orange saturation) diagonal block. Of the demographic factors sex in particular was negatively correlated with select behavioral instruments/subscales suggesting that males (coded 1 in analyses) scored lower for these

instruments/subscales compared to females. (B) Transdiagnostic subgroups show greater variation along PC1-axis, that is (C) a weighted-average of all input variables. The clusters showed significant difference in PC1 scores, with cluster 1 loading higher (more negative PC1 score) than cluster 2. correlation was estimated through Spearman's method. (**D**) Partial least squares discriminant analysis (PLS-DA) for the predictors of case-control status. The sample biplot depicts projection of study participants along first and second PLS components (x and y axes). Similar to our PCA projection, PLS component 1 appears to discriminate participants best, although discrimination is not clear or exclusive (overlap is notable). The plot also provides a premise on how novel samples would be classified based on position of along prediction background (blue and orange background) predicted given PLS-1 and PLS-2 scores. (**E**) PLS component 1 (X-variate) showed greatest covariance with Y-variate (71% explained variance) with BASIS-24 derived depression/functioning subscale, and anxiety loading most heavily in the component. These variables could thus be conceived as the most 'important' predictors of cluster labels for participants. Substance use dimensions in contrast, had marginal influence on clustering outcome.

Symptom scales that contributed most to separation of clusters

We used PLS-DA (**Figure 2D**) to find the weighted function of the 15 input variables (psychological instruments and substance use measures) that most accurately discriminated between C1 and C2. The first PLS component (X-variate 1) accounted for a large proportion (71.4%) of the variability in cluster assignments (**Figure 2D-E**). Consistent with our PCA results, BASIS-24 derived subscales (depression/functioning, emotional lability, self-harm), anxiety (GAD-7 total), and BPD (MSI-BPD total) were highly weighted on the first PLS component (-0.83, -0.36, -0.29 respectively; arbitrary unit), suggesting that a combination of these variables contributed most to C1/C2 assignment (**Figure 2E**). SHAPS and substance use instruments did not contribute greatly to clustering outcome as these were only more minimally different between clusters. SHAPS, HSI, DAST-10 and AUDIT-C also showed more limited variance in distribution within the cohort (**Figure S3C**).

Brain functional connectivity differences

In Part 2 of our analyses, we examined brain FC differences between the C1 (N=25) and C2 (N=11). Examining distributions, relative to C2, C1 consistently had higher FC at global-level

(**Figure 3A**; µC1—C2 = 3.16—2.76; KS-statistic = 0.37, P=0.19) and edge-wise (**Figure 3B**; FC range: C1=-3.16–166.02, C2=-2.69–142.34; KS-statistic=0.13; P<0.0001). Across all intermodular connectivity, C1 generally had significantly higher FC than C2 (**Figure 3C**; FC range: C1=0.67–7.83, C2=0.43–8.22; KS-statistic =0.28; P<0.0001). Examination within specific module pairs showed nominal significance between the subcortex and three other networks: limbic ($P_{uncorrected}$=0.043), default mode ($P_{uncorrected}$=0.043) and fronto-temporo-parietal ($P_{uncorrected}$=0.041), with mean connectivity being higher in C1 than C2 (**Tables S2-3**). At nodal-level, FC 33/360 cortical regions - including those within the dorsolateral prefrontal cortex (left p9-46v left area 46), anterior cingulate and middle prefrontal cortices (left p24), orbitofrontal cortex (left OFC), ventral visual stream (right VMV2), frontal and posterior opercula (left/right FOP1, right pFop), insula (left MI), somatosensory cortices (right area 3b,24dd) - and the left accumbens were higher in C1 than in C2 (**Figure 3D;Tables S3-4**). However, these differences did not survive FDR correction. Within functional modules (intramodular), the visual and ventral attentional networks had greatest differences between the clusters. However, these differences were not significant (**Figure 3E**).

Figure 3: Brain functional connectivity differences in symptom-driven clusters. (A) Functional connectivity was not significantly different between clusters at global-level (estimated at individual-level). lHowever, significant difference in distribution was observed

at **(B)** edge-wise (connection-wise; estimated from group-averaged connectivity matrices), and **(C)** at intermodular-level (between intrinsic functional networks; estimated at individual-level) with cluster 1 (C1) consistently showing stronger connectivity than cluster 2 (C2). **(D)** Few regions (nodes) showed nominal statistical significance. These include regions within the prefrontal cortices and opercular areas, with C1 showing stronger connectivity (more green/blue) than C2. **(E)** Intramodular (within functional networks) connectivity was not significantly different between clusters, although C1 again had generally higher connectivity (deeper blue intensities) that C2. *statistical comparison was performed using Kolmogorov-Smirnov test.*

Sex-related behavioral and neurological differences within symptom clusters

As C1 had a significantly greater proportion of females than C2 (see Results 'Cluster Identity'), we elected to further examine sex-related differences pre-clustering and within-cluster, in behavioural instruments most predictive of cluster assignments (BASIS-24 depression and GAD-7), as well as instrument with the greatest difference in terms of effect size (QIDS total score). Prior to clustering, females had significantly higher BASIS-24 derived depression/functioning (P<0.0001; µF|µM = 18.68639 | 16.09116), anxiety (GAD-7 total; P<0.0001; µF|µM = 13.92995 | 12.74217) and QIDS (total; P<0.0001; µF|µM = 16.53076 | 14.32249) scores than males (**Figure 4A-C** left panels). This observation persisted following clustering, where in both clusters, females similarly, had higher BASIS-24 derived depression/functioning (C1|C2; P<0.0001 | P<0.0001; µF: 22.43277 | 13.85366; µM: 21.19335 | 11.79389), and QIDS (C1|C2; P<0.0001 | P<0.0001; µF: 19.88248 | 12.18560; µM: 18.86 | 10.51) scores compared to males (**Figure 4A,C** right panels). Post-hoc analyses revealed that cluster-by-sex interaction effect was not significant for BASIS-24 depression [F(1, 1565) = 2.732, sumsq:65, meansq:65, p=0.0986] and QIDS [F(1, 1526) =2.427 p=0.119], but was so for GAD-7 [F(1, 1565) =12.447, p=0.000431], given the opposite trend i.e., males higher than females, was noted within C1 (C1|C2; µF: 16.87234 | 10.067039; µM: 17.34688 | 8.884817). Nonetheless, this difference was not significant (C1|C2; P=0.066 | P<0.0001) (**Figure 4C** right panel). Validation using discharge data supported this sex-related observations, and further demonstrated consistency for GAD-7 as well. Before and after clustering, significant sex differences were observed for BASIS- 24 depression/functioning (P<0.0001), QIDS total score (P<0.0001), and anxiety (GAD-7 total score; P<0.0001) (**Figure S5**). In relation to MRI findings, we elected to examine sex-related differences at intermodular-level upon observing the greatest between-cluster difference

across intermodular FC distributions (see Results Brain functional connectivity differences). Overall, males had significantly higher intermodular FC compared to females (rangeM | rangeF = 0.837 - 8.218 | 0.434 - 5.723, D = 0.26701, p-value = 1.332e-15) (**Figure 4C** left panel). This observation was consistent within each cluster, in that males had significantly greater intermodular FC than females in C1 (rangeM | rangeF = 0.837 - 7.829 | 0.673 - 5.723; KS-statistic =0.31708; P<0.0001) and C2 (rangeM | rangeF = 0.963 - 8.218 | 0.434 - 3.821; KS-statistic =0.265; P=0.0003785) (**Figure 4C** right panel).

Figure 4: Sex-related differences within symptom-driven clusters. (A-B) Across behavioral instruments most predictive of clustering assignments, females consistently had higher scores suggesting greater severity endorsement than males, evident prior to clustering and within clusters. **(C)** By-sex intermodular-level (between intrinsic functional networks; estimated at individual-level) comparison before and after application of cluster assignments consistently showed statistically stronger connectivity in males compared to females. cluster 1 (Nmale | Nfemale = 13|12), cluster 2 (Nmale | Nfemale = 8|3). *statistical comparison was performed using Kolmogorov-Smirnov test.*

DISCUSSION

In the current investigation, we present findings broadly supporting the transdiagnostic frame work or dimensional approach to psychiatry. As hypothesized, our initial clustering analysis on self-reported mental health symptom and substance use questionnaires yielded patient clusters or transdiagnostic subtypes, that differed in severity of psychopathology, in particular depression and anxiety. Next, as predicted by our second hypothesis, we also demonstrated that the variation in acuity was coupled with brain functional connectivity differences between intrinsic resting-state networks (intermodular connections), spanning brain-wide connections.

Single-diagnostic vs Transdiagnostic subtyping

Clustering and subtyping approaches are not new in psychiatry. Nonetheless, the majority of extant subtyping reports have typically focused on single-disorder subtyping, that is, discovery of subgroups within a single diagnostic category such as major depressive disorder (MDD), post-traumatic stress disorder (PTSD) and schizophrenia (18). While there is irrefutable value in such clustering efforts, Grisanzio et al. (2018) (18) accurately depicted a crucial gap that is not met through single-disorder subtyping - it 'cannot address the need to characterize the heterogeneity and overlap of symptoms across diagnostic categories'. While psychiatric research has evolved over the past two decades exploring various transdiagnostic constructs/types e.g. within-spectrum (5), transdiagnostic subtyping that seek to classify patients beyond diagnostic criteria is arguably an important nascent research subdomain in psychiatry. As such, few studies have employed a comparable study design to the present investigation i.e. utilizing behavioral or mental health questionnaires as clustering variables. A previous study performed hierarchical clustering in a group of patients with primary diagnoses of either MDD, PTSD, and panic disorder, with comorbidity present (18). Analysis on self-reported negative mood, anxiety, and stress symptoms – ascertained through Depression, Anxiety and Stress Scale, version 21 (DASS-21) – yielded six transdiagnostic subgroups that differed in symptom profiles e.g. normative mood, anhedonia subgroups. This finding is unlike our outcome where resultant clusters were discriminated by acuity of symptoms, rather than psychopathological profiles. Another study [19] included risk factors, antecedent variables and concomitant indices that are associated with mental health

disorders in adulthood such as general health, life events questionnaire (LEQ), childhood trauma questionnaire (CTQ) indices, maternal/paternal bonding and intelligence quotient (IQ). Using a discovery sample of N=1,250 (including N=590 health controls), the analysis yielded five clusters, where the first subgroup was mainly healthy controls, and remaining subgroups comprised distinct profiles of diagnoses, symptoms, and environmental risk factors. For the purpose of our analysis, we only included indices of mental health symptoms and related outcomes e.g. substance use, as opposed to risk factors. We designed our investigation in part to simplify interpretation of resultant transdiagnostic subgroups, and acknowledging the suggestion by Maj (2018) (40) who noted the need for a more detailed characterization of psychopathology of the individual case. Nonetheless, the author also emphasized the value of concurrent analyses unpacking vulnerability and protective factors, alluding to the exploration of antecedent variables such as family history, early environmental exposures, and the assessment of concomitant variables such as personality traits, socioeconomic status/resource, as well as cognitive functioning.

In relation to our Part 2 analyses on functional connectivity, while we note between-cluster differences, it is challenging to contextualize our findings with respect to wider research as extant studies on transdiagnostic subtyping have yet to characterize resultant clusters based on brain functional connectivity (18). Further, as discussed above, identity of our clusters was distinct from those in previous studies. It is worth noting however that currently, the weight of the literature on transdiagnostic subtyping stems from biotyping, that is, clustering of biological markers e.g. MRI markers (41–44), neurocognitive dysfunction (45). Such studies recognized that as with behavioral symptoms, there is also considerable overlap across diagnoses in regions showing abnormal connectivity, measured both functionally (i.e., temporal correlations between spatially disparate brain regions) and structurally (i.e., integrity of connecting white matter tracts of the brain) (43). A similar study focused on MDD utilized a more limited set of symptoms (Beck's Depression Inventory-I; Beck's Anxiety Inventory) for clustering (46) and reported associated frontotemporal network abnormalities between clusters that showed variations in symptom class. However, our current findings on intermodular and edge-wise differences perhaps conceptually align more with the cross-disorder brain dysconnectivity model that argues that 'common symptoms arise from common circuit dysfunction' (47). Indeed, emerging studies have begun reporting neural signatures that linked with transdiagnostic risk factors (12, 13, 48, 49). Thus, it is conceivable that behavioral symptom-driven clustering could reveal related brain functional network differences that cut across several diagnostic criteria that share psychopathologies.

Sex-effects in self-reporting of mental health symptoms and implications on transdiagnostic psychiatry

We also observed sex-related differences upon cluster characterization that are worth discussing in the context of transdiagnostic and further, precision psychiatry. First, to emphasize, the analytic cohort was very balanced in terms of sex distributions (46.1% Male). We were additionally aware of potential recruitment unit biases e.g. existence of an all-female inpatient unit that could have disproportionately contributed to patient recruitment. However, male and female patients were represented across all five recruitment units within the initial analytic cohort, as well as within clusters (**Figure S6**). Within-cluster, females consistently scored significantly higher in instruments most predictive of the cluster assignments. These observations were not confounded by sex-imbalance in our analytic cohort as the inpatient population was sufficiently balanced at approximately 50:50. Further, cluster-by-sex interaction effect was null, suggesting that sex differences observed in questionnaire outcomes is independent of cluster assignments. Rather, this is indicative of a main discrepancy in psychopathological experience – as ascertained by mental health questionnaires – between inpatient females and males. We venture that these observations could be attributable to (i) females generally experiencing more severe mental health symptoms than males, (ii) sex-related healthcare/treatment disparities, or (iii) under-reporting of mental health symptoms in males. Historically, investigators have argued that sex-related differences are attributable to reporting bias and not actual difference in illness (50, 51), including mental health (52). Contradicting this, a more current study reported a sex-related 'health gap' (53) based on self-reported health with survey data collected across 59 high income countries. The authors found that women generally experienced 'poorer' health than men, especially in angina, arthritis and depression where female excesses of 33%, 32% and 42% respectively were estimated. Females more frequently endorsed more 'extreme' and/or 'severe' responses when reporting impairments within disease/disorder categories. The authors did note that health service utilization by females tended to be at least equal or higher than that for males in virtually all countries, and thus differential access is likely not confounding prevalence of health problems, unless the quality of treatment received differed greatly in all societies. The likelihood of this i.e. receipt of differential treatment in males vs females undergirds our second conjecture as to why females reported higher levels of mental health severity. 'We have studies of fruit flies, mice, hamsters, frogs, monkeys, and men with this condition – but medical research using women as subjects just never occurred to anybody.' – this caption from a 1991 editorial cartoon illustration (54) rather presciently introduced a key issue within healthcare research. Today, this has led to a healthcare system that is not attuned to female clinical presentations (55), heavily evidenced through studies on cardiovascular health (56–59) and pain management (60–62). In relation

to psychiatric care, the 2021 Office for National Statistics (ONS) UK survey found that women struggled to attain 'legitimacy' for symptoms experienced during mental health crisis such as panic attacks or an episode of psychosis (63). The ONS asked more than 2,000 women about their experiences and reported that a third said they were asked if they were "overthinking things", 20% were asked if they were on their period, and a further 22% of the women feared being seen as "attention-seeking". Thus, it is conceivable that to attain equitable levels of care to males, females would resort to presenting more severely at point-of-assessment (55, 64). In contrast, ideas on symptom perception perhaps offer partial support to the third hypotheses. Shi et al. (2021) (65) reported that in the case of depression where a preponderance of females is noted, females tend to report more mild–moderate symptoms than males due to a more 'feminine coping style' and are thus more willing to express affective symptoms, as well as seek help. Contrastingly, a 'masculine coping style' is centered on being emotionally unexpressive, and lower tendency to seek help. Therefore, under-diagnoses and under-treatment on depression in males was a function of under-reporting.

In relation our neuroimaging findings, we note that even following attrition attributed to un-availability of MRI scans, Male:Female composition between-clusters was comparable to Part 1 analyses in that C1 had more females, compared to C2 (C1; 50% males, C2;72.7% males). As such, on the one hand, observed differences in FC could be attributable to cross-symptom acuity/severity i.e. a transdiagnostic brain biomarker, or, on the other hand could be extrapolated to suggest sex-differences in functional connectivity patterns related to transdiagnostic symptoms. Neuroimaging related sex differences are arguably better-studied in the context of depression, including cerebral perfusion, structural and functional connectivity patterns (66). Some studies have also suggested that neuroimaging differences could be a product of sex and age interaction in mental disorders (67–69). We observed a significant difference in age between males and females in our cohort, and further within clusters Figure S5C, with females being younger than males. However, these effect sizes were small, and we did not observe a main difference in age in non-sex-stratified cluster characterization (although age was marginally higher in C2). As such, we conclude that the observed FC differences were likely a product of transdiagnostic severity.

Strengths & limitations

In light of the discussed findings, we noted key strengths of our study to be (i) use of varied and multiple self-reported instruments for psychopathology assessment, as well as (ii) a

large, sex-balanced sample with a wide age range. Also noteworthy, we observed concordant findings to single-disorder data-driven clustering approaches i.e. the most common finding being total severity differences (20) that is yet to be demonstrated by previous transdiagnostic subtyping investigations. Therefore, our fundings argue that transdiagnostic subtypes are not simply a product of different symptom profiles, but also coupled with acuity of these symptoms. We also supported our cluster characterization with neuroimaging findings, although in a much more limited subset of participants. Taken together, we advocate for an interfacing between the RDoC and HiTOP framework, emphasizing both biobehavioral abnormalities and dimensional/spectral assessments of psychopathology (rather than binary per DSM). Taking heed from a report by Saunders et al. (2023) (70), we especially advocate for the integration/introduction of sex- and gender-specific surveys, diagnostic criteria, as well as treatment plans owing to the discrepancies in self-reporting of symptoms observed here. The typical handling of sex and gender in psychiatry research, and research at large has been as to consider these as 'confounders' and/or 'biases'. In actuality, these are integral components of health and ill-health experience i.e. arguably, part of the disease/disorder that translate to related biological signatures.

An important limitation of our study is that we were unable to access clinical diagnoses i.e. primary diagnoses to confirm utility/accuracy of transdiagnostic status of our study cohort, though the majority of patients on the included units had primary diagnoses of MDD or anxiety related disorders. As all recruitment sites were represented in our sample, we interpreted the resultant cohort as transdiagnostic, comprising patients with both mood disorders, trauma and stressor-related disorders, and personality disorders (per DSM-V). We are at present unable to determine the proportion of these diagnoses within each cluster, although we note that this information would help to further understand and interpret the current findings. We also note that unlike previous investigations (18), our study design did not include a replication cohort. Nonetheless, we judiciously mitigated issues surrounding robustness and stability of clustering solution by implementing the clustering algorithm through consensus clustering with subsampling, as well as using unobserved discharge data to independently validate cluster identity. Our present investigation also did not include any healthy controls as the principal population were hospitalized psychiatric patients i.e. inpatients. Arguably, including healthy controls in the analysis might statistically confound clustering process in that results clusters could be controls vs cases, rather than desired subgroups of cases. Future research could incorporate psychiatric outpatients as an intermediate comparison group, alongside health controls which aligns with an alternative approach to psychiatric diagnostics i.e. symptoms are a continuous function, and deviations

could be represented through normative modelling (71). We also noted over our literature search on sex disparity in healthcare that the term 'gender' was frequently used in some early reports when 'sex' was meant. We were careful to not misrepresent findings from these studies, and further ensured that the authors clearly intended to examine sex differences despite using the word 'gender'. Finally, we acknowledge that various clinical factors e.g. disease burden (duration of disorder, non-psychiatric comorbidities), admission history e.g. first hospitalization vs repeat, and sociodemographic variables e.g. race/ethnicity, educational background, socioeconomic status could equally moderate health experience, and therefore influence self-reporting of symptoms. This protected information was less available for our research use. However, consideration of these variables in future studies utilizing self-reported symptom scales is crucial.

CONCLUSIONS

In conclusion, findings from this cross-sectional study suggest that heterogeneity within transdiagnostic inpatients was defined mostly by severity of mental health symptoms across various domains, and not by specific symptom profiles. Further, the neuroimaging observations point towards a putative transdiagnostic biomarker, supporting existing notions on 'shared symptoms, share neurological dysfunctions'. The present results also suggest that these biobehavioral properties are linked with sex, a factor that should be examined more closely in context of transdiagnostic psychiatry.
