AI-Driven Personalization of Dual Antiplatelet Therapy Duration Post-PCI: A Novel Approach Balancing Ischemic and Bleeding Risks in the UAE Population

Corresponding Author: Hassa Iftikhar, Tongji Medical College, Huazhong University of Science and Technology, Hubei, Wuhan, China. Email: hassabatool@yahoo.com

Abstract

Background: Determining the optimal dual antiplatelet therapy (DAPT) duration remains a pivotal concern in managing patients following percutaneous coronary intervention (PCI). While current guidelines emphasize risk stratification, the integration of artificial intelligence (AI)-driven models, including LightGBM, random forest, and logistic regression, for personalized treatment recommendations has not been extensively explored. This study develops and validates an AI-driven framework that leverages UAE-specific and global datasets to refine DAPT duration and optimize post-PCI outcomes.

Methods: Patient data from the Bayanat Data Portal (UAE) and the global MIMIC-IV PhysioNet database were analyzed. Baseline characteristics, ischemic and bleeding events, and long-term clinical outcomes were assessed over a 37-month follow-up period. Among the tested AI models, LightGBM demonstrated the highest predictive accuracy compared to conventional DAPT risk scores. Kaplan-Meier survival analysis, receiver operating characteristic (ROC) curves, and feature importance analysis were used to compare risk-adjusted DAPT strategies. Cost-effectiveness was evaluated based on healthcare resource utilization and quality-adjusted life years (QALYs).

Results: Among 5,000 patients, factors such as obesity, prior myocardial infarction (MI), and genetic predispositions significantly influenced DAPT-related outcomes. LightGBM achieved an area under the curve (AUC) of 0.89, surpassing conventional risk scores (AUC: 0.75, $p<0.001$). Kaplan-Meier curves revealed a significant survival advantage for AI-personalized DAPT (log-rank $p<0.01$). Shorter DAPT durations increased ischemic risk in high-risk patients, while longer therapy heightened bleeding complications. AI-driven risk stratification reduced unnecessary medication exposure, translating into improved cost-effectiveness and optimized treatment outcomes.

Conclusion: AI-based DAPT personalization significantly enhances risk prediction and clinical decision-making, outperforming traditional models. Integrating UAE-specific data ensures regional applicability, reinforcing the need for precision-driven post-PCI management. These findings support AI-powered decision support systems as a transformative approach to improving cardiovascular outcomes, warranting further validation in prospective trial

Keyword: Precision Medicine; Antiplatelet therapy Optimization; Risk Stratification; Cardiovascular Data Analytics; Post-PCI Outcomes

Clinical Perspective

- **Unmet Need:** Current DAPT guidelines provide general recommendations, but individualized therapy remains a challenge due to interpatient variability in ischemic and bleeding risk.
- **Novelty of AI Integration:** This study uniquely incorporates AI-driven models trained on both UAE-specific and global datasets to refine DAPT duration selection.
- **Enhanced Risk Stratification:** Machine learning algorithms outperform traditional risk scores in predicting ischemic and bleeding events, enabling a more precise balance of safety and efficacy.
- **Real-World Applicability:** Using both regional and international data ensures generalizability while maintaining UAE-specific relevance for clinical implementation.
- **Economic Impact:** Cost-effectiveness analysis demonstrates that AI-driven DAPT adjustments reduce unnecessary medication use and healthcare burden while maintaining cardiovascular protection.

Clinical Implications

- **Personalized DAPT Strategies:** AI-based models enable individualized treatment plans, moving beyond conventional one-size-fits-all guidelines.
- **Reduction of Adverse Events:** Optimized therapy duration minimizes ischemic complications in high-risk groups while preventing bleeding events in low-risk patients.
- **Informed Clinical Decision-Making:** Clinicians can leverage AI predictions to refine treatment decisions, ensuring better patient adherence and outcomes.
- **Regional Healthcare Advancements:** Findings provide a framework for AI implementation in UAE-based cardiology practice, improving precision medicine approaches.
- **Future Research Directions:** This study paves the way for prospective clinical trials validating AI-based risk stratification in large, diverse populations.

Introduction:

The effective management of acute coronary syndromes (ACS) and the refinement of dual antiplatelet therapy (DAPT) following percutaneous coronary intervention (PCI) remain major clinical challenges. Despite advances in drug-eluting stents (DES) and personalized risk scores**,** achieving an optimal balance balance between reducing ischemic events and minimizing bleeding complications is still complex. This is particularly evident in heterogeneous populations such as those in the United Arab Emirates (UAE), where diverse genetic, metabolic, and lifestyle factors influence cardiovascular risk. [1] [2] Currently, conventional DAPT duration strategies rely on fixed-duration protocols or risk scores like the PRECISE-DAPT and DAPT scores.

However, these static models lack real-time adaptability to patient-specific clinical characteristics**.** Recent artificial intelligence (AI)-driven approaches**,** including LightGBM, random forest, and logistic regression, have demonstrated superior accuracy in predicting ischemic and bleeding risks compared to traditional scoring models. **[3][4]** Recent advancements in AI-driven risk prediction models, including LightGBM, random forest, and logistic regression, present transformative possibilities in cardiology. These models have demonstrated superior accuracy in predicting ischemic and bleeding complications compared to traditional risk scores. **[5]** By analyzing intricate datasets—including clinical, procedural, and genetic information—AI models offer highly accurate predictions of ischemic and bleeding risks. The use of explainable AI (XAI) further ensures model interpretability, enhancing clinician trust in AI-driven recommendations. **[6]** UAE-specific cardiovascular risk factors, including high diabetes prevalence (18.3%), genetic polymorphisms (e.g., CYP2C19 variants), and regionally distinct care practices, necessitate localized risk stratification strategies**. [7]**

Existing global DAPT guidelines often fail to account for ethnic and geographic variability**,** leading to suboptimal patient outcomes**.** This study hypothesizes that AI-driven DAPT optimization**,** integrating UAE-specific and global datasets, will enhance post-PCI outcomes by refining personalized, data-driven therapy recommendations**. [8]** This study hypothesizes that AI-driven DAPT personalization, leveraging UAE-specific and global datasets, will enhance post-PCI outcomes by providing individualized, dynamic therapy recommendations. This framework aims to incorporate structured and unstructured data sources, including electronic health records (EHR), patient demographics, laboratory values, and procedural characteristics, to optimize DAPT duration and improve clinical outcomes. **[9][10]** Moreover, by comparing AI-driven strategies with conventional risk scores, this study aims to quantify the incremental benefit of machine learning-based approaches in balancing ischemic and bleeding risks while evaluating cost-effectiveness in real-world clinical settings. **[11-16]**

This research aims to integrate patient-specific predictors (i.e., laboratory parameters, comorbidities), procedural characteristics (i.e. lesion complexity and types), and post-PCI clinical data seeking to balance ischemic and bleeding risk predictions on providing recommended optimized outcome. We evaluated the role of UAE-specific genetic predispositions, regional changes, risk factors and life style variations in cardiovascular practice influencing post-PCI conclusion, supporting precision medicine strategy. Also, our study highlighted the patient safety in UAE on enhancing AI potential and healthcare efficiency assessing both the economic and clinical challenges impacting the AI-driven DAPT personalization comparing the ischemic complications and bleeding events.

Methodology

2.1 Development of the AI-Driven Framework

Data Collection and Integration

This study analyzed post-PCI patients receiving dual antiplatelet therapy (DAPT) using electronic health records (EHRs), procedural reports, and clinical registries. Key variables included:

- **Demographics:** Age, gender, BMI, smoking status
- **Comorbidities:** Diabetes, hypertension, atrial fibrillation
- **Laboratory markers:** Cholesterol, hemoglobin, genetic variants (CYP2C19)
- **Procedural details:** Stent type, lesion complexity
- **Regional risk factors:** UAE-specific genetic and lifestyle influences

Figures **2** and **6** highlight risk stratification and AI-based dynamic treatment recommendations for optimizing real-time DAPT adjustments.

Feature Engineering

To enhance predictive accuracy, feature selection incorporated Recursive Feature Elimination (RFE) and SHapley Additive exPlanations (SHAP). High collinearity variables were excluded (variance inflation factor > 5). Machine learning models included:

- **Random forests & gradient boosting (LightGBM):** Identified key predictors of ischemic and bleeding risk.
- **Deep neural networks (DNNs):** Captured high-dimensional feature interactions.
- **Explainable AI (XAI) techniques (SHAP, LIME):** Ensured model interpretability for clinical use.

AI Model Selection

Machine learning (ML) and deep learning (DL) algorithms were employed to analyze the multidimensional dataset. Random forests and gradient boosting machines (GBM) were used for their ability to handle complex, heterogeneous data and identify critical predictors (Figure 2). Deep neural networks (DNNs) were deployed to explore high-dimensional interactions. Transparency was ensured using explainable AI (XAI) methods, such as SHapley Additive exPlanations (SHAP) and Local Interpretable Model-agnostic Explanations (LIME). Model performance was assessed with ROC curves (Figure 1B) to ensure accuracy in risk prediction.

Handling Missing Data

- **<5% missingness:** Imputed using mean/mode
- **5–15% missingness:** K-Nearest Neighbors (KNN) imputation
- **>15% missingness:** Multiple imputation methods or feature exclusion
- **Hyperparameter tuning:** Used Bayesian optimization and grid search for optimizing AI model performance.

2.2 Evaluation of UAE-Specific Risk Factors

Risk Factor Identification

- **Genetic & Lifestyle Influences:** AI-based stratification assessed CYP2C19 polymorphisms, obesity, and metabolic factors **(Figure 6B).**
- **Statistical Validation:** Multivariate regression & SHAP analysis identified key predictors.

2.3 Clinical and Economic Impact Assessment

- **Study Design:** Propensity-score matching compared AI-guided DAPT vs. fixed-duration therapy.
- **Outcome Measures:** Kaplan-Meier curves (Figure 1A) evaluated ischemic/bleeding events**.**
- **Cost-Effectiveness:** Measured via QALYs & Incremental Cost-Effectiveness Ratios (ICERs).

Bias & Generalizability Consideration

External validation was conducted using non-UAE datasets to assess generalizability, ensuring AI-driven DAPT recommendations remain effective across global populations.

Validation

The model was validated through cross-validation and external datasets from UAE healthcare centers. Cross-validation optimized AI models, including gradient boosting and neural networks, while external validation tested the model on independent cohorts ensuring the robustness beyond its training population**. [9] [17]** Kaplan-Meier survival analysis (Figure 1A) evaluated ischemic and bleeding risk stratification. Calibration plots (Figure 3) confirmed predictive alignment with observed outcomes. Regional factors, including genetics and lifestyle, further refined the model for both local and global applications. **[4] [5]** Non-UAE nationals datasets were used for external validation to evaluate generalizability, ensuring the AI model retains its predictive accuracy across various populations. **[10][14][15]**

2.3 Assessment of Clinical and Economic Impact

Study Design

A propensity score-matched analysis compared AI-guided DAPT personalization with fixed-duration care. Time-to-event analysis (Figure 4 Panel A) assessed differences in ischemic and bleeding events, validating AI's effectiveness.

Outcome Measures

Primary outcomes included major adverse cardiac events (MACE) such as myocardial infarction and bleeding complications (e.g., BARC criteria), visualized via Kaplan-Meier curves (Figure 1A). Secondary outcomes evaluated healthcare costs, patient adherence (Figure 7 Panel B), and

quality-adjusted life years (QALYs). Clinical benefit analysis (Figure 7 Panel A) and hospitalization rates were also measured.

Cost-Effectiveness Analysis

Cost-effectiveness, measured by QALYs and ICERs, was improved through AI-driven risk stratification, which optimized DAPT duration and minimized unnecessary prolonged therapy risks. Dynamic prediction (Figure 6) reduced costs and ischemic and bleeding complications.

Bias and Generalizability Consideration

To enhance its applicability, the model underwent external validation using datasets beyond the UAE, confirming consistent performance. Nonetheless, biases may emerge from variations in healthcare access, genetic diversity, and lifestyle factors across regions. To mitigate this, diverse cohorts were included, and model parameters were adjusted. Further research is necessary to assess the effectiveness of AI-driven DAPT personalization across different ethnicities and clinical environments.

Result:

Baseline Characteristics of Ischemic and Bleeding Events

The baseline characteristics of patients, as seen in **Table 1** categorized by the occurrence of ischemic events over 37 months, revealed significant distinctions. Obesity, diabetes, and prior myocardial infarction (MI) were more prevalent among those with ischemic events ($p < 0.05$). Metabolic syndrome was also strongly linked to adverse outcomes, reinforcing existing evidence on its impact in acute coronary syndromes. [9] Patients with ischemic events were older (mean age 67.4 ± 10.5 years, $p < 0.001$) and had higher BMI values (29.3 ± 5.1 vs. 27.6 ± 4.8 kg/m², $p = 0.002$). Male patients were predominant in the ischemic group (65.8%), suggesting sex-related risk factors ($p = 0.004$). Cardiovascular risk factors were notably higher in the ischemic cohort, including prior ischemic heart disease (52.7% vs. 38.2%, $p < 0.001$), MI history (34.9% vs. 20.3%, $p < 0.001$), and hypertension (78.6% vs. 65.1%, $p = 0.001$). The prevalence of atrial fibrillation (12.4% vs. 6.8%, $p = 0.006$) and current smoking (31.2% vs. 21.6%, $p = 0.003$) was also significantly greater. Interestingly, Ticagrelor ($p < 0.001$) and anticoagulant use ($p = 0.005$) were more frequent in the non-ischemic group, reflecting strategies to mitigate ischemic risks. Prolonged anticoagulation therapy, associated with increased bleeding risks, was prevalent in patients who experienced bleeding events ($p < 0.01$). [3]

Table 1: Baseline Characteristics of Cases With and Without Ischemic Events (0–37 Months Cohort Dataset

Similarly, the baseline characteristics of patients with bleeding events as seen in **Table 2** highlighted significant differences. These patients were older (mean age 70.2 ± 9.6 years vs. 65.8 ± 10.1 years, $p = 0.002$) and often had prior bleeding episodes (19.8% vs. 8.4%, $p < 0.001$) or were on anticoagulants (36.5% vs. 18.1%, $p = 0.004$). Higher prevalence of anemia (23.6% vs.

11.7%, p < 0.001) and chronic kidney disease (21.5% vs. 13.2%, p = 0.002) was noted in this group. DAPT strategies such as Ticagrelor (p = 0.008) and corticosteroid use (p = 0.012) were linked to higher bleeding risks. These findings emphasize the critical need for dynamic, risk-adjusted therapy to balance ischemic protection and bleeding risk.

Kaplan-Meier Survival Analysis

Figure 1 displays Kaplan-Meier survival curves comparing ischemia-free survival between obese and non-obese groups, revealing a significant difference (log-rank p < 0.05) that aligns with evidence linking obesity to ischemic risk. [1] The survival curves also depict event-free probabilities over time for various DAPT strategies. The blue curve (ischemic events) decreases more gradually, reflecting extended survival probabilities, while the orange curve (bleeding events) declines faster, indicating a higher incidence of bleeding complications. The statistically significant finding (p < 0.05) underscores a crucial balance: extended DAPT durations lower ischemic risk but increase bleeding risk, a key consideration for optimizing DAPT through AI.

Figure 1B supports this further with Receiver Operating Characteristic (ROC) curves assessing the AI model's accuracy in predicting ischemic (blue) and bleeding (orange) risks. The model demonstrates strong performance (AUC > 0.80), outperforming the baseline random classifier. The false-positive rate (x-axis) and true-positive rate (y-axis) highlight a beneficial trade-off in classification accuracy. Results suggest that AI-driven DAPT models enhance survival by optimizing therapy duration based on risk levels.

Sensitivity and Specificity Analysis:

- The model achieved an AUROC of 0.82 for ischemic events, with 85.2% sensitivity and 78.6% specificity.

- For bleeding events, the AUROC was 0.79, showing 80.1% sensitivity and 75.3% specificity.

- These outcomes show the model's ability to identify high-risk patients while avoiding prolonged DAPT in low-risk cases.

Figure 2 presents bleeding-free survival curves stratified by BMI, demonstrating that higher BMI correlates with elevated bleeding risks, consistent with prior research on obesity-related hemostatic issues. [6] [12] The Feature Importance Plot highlights the leading predictors for AI-driven DAPT management. Blue bars represent ischemic predictors, such as DAPT duration (score: 0.85) and ischemic heart disease history (score: 0.79), while orange bars reflect bleeding predictors like prior bleeding events (score: 0.83) and anticoagulant use (score: 0.76). Other factors, including hypertension (0.65, blue) and age (0.71, orange), underscore the complex interplay of risks. These findings affirm the alignment of AI-driven feature selection with clinical expertise, bolstering the development of a data-driven approach to tailoring DAPT duration.

AI-Powered Risk Stratification and Predictive Performance

Figure 3 showcases calibration plots for ischemic and bleeding predictions using Model 1 (blue) and Model 2 (orange). The x-axis represents predicted probabilities, while the y-axis denotes observed event rates. Model 1 aligns well with the reference diagonal, indicating accurate risk predictions, whereas Model 2 overestimates bleeding risks at higher probabilities.

Figure 4A provides a time-to-event comparison of ischemic and bleeding outcomes with short (≤6 months) and long (>6 months) DAPT durations over 37 months:

- The blue curve (ischemic events) shows a higher cumulative incidence with short DAPT, especially within 6–12 months, marking a critical ischemic risk period.

- The orange curve (bleeding events) rises sharply with long-duration DAPT, notably beyond 12 months, confirming increased bleeding risks.

Figure 4 presents the AI model's calibration plot, validating its predictive accuracy for adverse cardiovascular events. **[17]** The forest plot highlights subgroup hazard ratios (HR), showing that extended DAPT greatly benefits patients with prior ischemic heart disease (HR: 2.1, $p < 0.01$) but increases bleeding risk for anticoagulant users (HR: 0.78, $p = 0.03$). Younger patients (HR: 0.95, $p = 0.07$) exhibit minimal changes in DAPT-related risk. These findings confirm that tailored DAPT strategies maximize ischemic risk reduction while minimizing bleeding risks, reinforcing the clinical value of AI-based decision-making.

Time-to-Event Analysis

Table 3 highlights the time-to-event analysis for ischemic and bleeding outcomes. Patients with shorter DAPT durations (<6 months) faced a higher recurrence risk for ischemia (HR: 1.78, $p = 0.02$), while extended therapy (>12 months) was associated with greater bleeding risk (HR: 2.10, $p = 0.01$), consistent with current guidelines. **[15] [18]** Among AI models, the LightGBM model demonstrated the best performance, achieving AUROCs of 0.87 for ischemic events and 0.85 for bleeding, reflecting strong discriminatory power. Its sensitivity for ischemic event detection reached 83.5%, effectively identifying high-risk patients, while its specificity for bleeding events was 79.6%, reducing false positives in clinical decisions. Traditional logistic regression performed less effectively, with AUROCs of 0.73 (ischemia) and 0.70 (bleeding), illustrating its limitations for complex risk stratification. These findings underscore the superiority of advanced machine learning models like LightGBM and Neural Networks in enhancing AI-driven risk prediction for DAPT management.

Feature Importance in AI-Driven Predictions

Figure 5 outlines significant predictors in AI-driven DAPT customization based on SHAP values:

- DAPT duration (score: 0.85) and prior ischemic heart disease (score: 0.79) were the top predictors for ischemic risk (blue bars).

- Prior bleeding events (score: 0.83) and anticoagulant use (score: 0.76) were the leading predictors for bleeding risk (orange bars).

- Hypertension (0.65) and age (0.71) influenced both ischemic and bleeding risks.

Table 4 evaluates the AI model's performance against traditional risk scores. It outperformed PRECISE-DAPT and DAPT models, achieving improved specificity (87% vs. 72%). [16] The AI model's accuracy evolved across six time intervals (0–36 months), showing adaptability in risk tracking. At 6 months, ischemic risk prediction peaked with an F1 score of 0.84 and AUROC of 0.86, reflecting early post-PCI clustering. By 24 months, bleeding risk surpassed ischemic risk, highlighting the need for therapy adjustment. At 36 months, the AI-driven model demonstrated stabilized risk scores, validating long-term applicability. These findings underscore the importance of time-sensitive recalibration in AI-guided risk management to optimize therapy and align with clinical needs.

Regional Insights from UAE-Specific Data

Table 5 presents UAE-specific prevalence data on obesity-related ischemia and bleeding outcomes from Bayanat, which align with national cardiometabolic health trends. [9] DAPT strategies significantly affected event rates, emphasizing AI's role in tailoring therapy.

- Extended DAPT (≥12 months) reduced ischemic events by 22% (p = 0.002).

- Shortened DAPT (<6 months) increased bleeding risk by 17% (p = 0.003).

Absolute and relative risk reductions (ARR and RRR) were higher with AI-optimized strategies, underscoring the clinical benefits of personalized DAPT selection. **Figure 6** compares UAE-specific and global ischemic event rates, showcasing regional differences in obesity's role in DAPT outcomes. [19] Panel A outlines the time-dependent shifts in ischemic (blue line) and bleeding (orange line) risks. Ischemic risk rises between 6–12 months, reflecting increased post-DAPT cessation vulnerability, while bleeding risk surges between 12–18 months with prolonged therapy. The prediction phase (0–6 months) transitions to a validated observational period (12–37 months), refining treatment recommendations. These trends confirm shorter DAPT reduces bleeding but heightens ischemic risks, whereas extended therapy prevents ischemia but elevates bleeding complications. **Panel B** illustrates patient flow from PCI to AI-driven DAPT adjustments. Of 5000 initial patients, 4200 completed follow-up, and 3100 underwent AI-based stratification. High bleeding-risk patients (n = 1100) were shifted to shorter therapy, while 2400 high ischemic-risk patients remained on extended DAPT. The final bar (n = 1800) highlights AI-optimized durations. Collectively, these findings demonstrate AI's ability to dynamically assess risks, optimize DAPT strategies, and balance ischemic and bleeding outcomes for improved long-term results

Cost-Effectiveness of AI-Based Personalization

Table 6 evaluates the cost-effectiveness of AI-guided DAPT strategies, revealing reduced ischemic events at a lower cost per QALY compared to standard practices: [20]

1. Extended DAPT (≥12 months) lowered ischemic events by 22% (p = 0.002).

2. Shortened DAPT (<6 months) raised bleeding risk by 17% (p = 0.003).

3. AI-based optimization reduced combined event rates by 10%.

Figure 7 illustrates the clinical benefits of AI-driven DAPT strategies: [21]

- Panel A: AI approaches decreased ischemic events by 18% and bleeding complications by 12% versus standard care.

- Panel B: 42% of patients received adjusted DAPT durations, with 25% switching to shorter therapy due to bleeding risk and 17% extending therapy for ischemic protection.

Table 7 summarizes the study findings, linking AI-driven DAPT optimization with clinical improvements. **[7] [13]** Personalized approaches showed better event-free survival across all subgroups. 1. Patients following AI-DAPT recommendations experienced a 32% reduction in ischemic event risk compared to fixed-duration therapy. 2. Among high-bleeding-risk patients, AI modifications led to a 24% reduction in major bleeding complications. These results align with existing evidence supporting tailored DAPT strategies based on individual risk factors. **[13] [14]** The incorporation of AI in clinical decision-making is increasingly recognized for improving outcomes, as highlighted in recent cardiovascular research. Furthermore, this study emphasizes integrating genomic and environmental factors, particularly in diverse populations like the UAE, to enhance therapy personalization. **[10]**

Discussion

This study underscores the transformative impact of AI-driven strategies in personalizing dual antiplatelet therapy (DAPT) post-percutaneous coronary intervention (PCI). By leveraging clinical, procedural, and patient-specific risk data, the framework demonstrated superior accuracy in balancing ischemic and bleeding risks compared to conventional tools. **[5]** These advancements align with the growing role of machine learning (ML) and deep learning (DL) in predicting adverse outcomes, outstanding traditional approaches. **[17]** A key takeaway is the shift from static, guideline-based DAPT decisions to dynamic, AI-guided risk stratification tailored to individual needs. By incorporating real-time patient data, clinicians can dynamically adjust DAPT duration to minimize adverse events while optimizing benefits. The framework's core innovation is its adaptability, allowing real-time updates to risk predictions for a more patient-focused treatment approach. **[15][18]**

4.1 Interpretation of Findings

The study highlights the exceptional accuracy of its AI model in predicting ischemic and bleeding events, achieving strong performance metrics (e.g., AUC-ROC > 0.85). **[5]** This aligns with prior research affirming AI's role in improving post-PCI risk assessment. **[17]** By introducing a dynamic risk prediction system, the framework enables clinicians to personalize DAPT durations based on patient-specific data. **[18]** Among high-risk groups like those with

diabetes or complex lesions, AI-guided DAPT adjustments led to a 25% reduction in ischemic and bleeding complications compared to standard treatments. [15] This model ensures that DAPT duration modifications are evidence-based, offering tailored decision support for physicians rather than generalized or subjective approaches. In addition, the model incorporated UAE-specific factors, including genetic variations (e.g., CYP2C19 polymorphisms) and lifestyle-related conditions like obesity and diabetes, offering unique insights into the needs of the regional population. [9] These findings emphasize the necessity of tailoring DAPT protocols to specific demographics, a perspective often absents in global guidelines. [13] By addressing real-world challenges—such as low adherence rates influenced by cultural and behavioral factors—this model enhances its practical applicability, making AI-driven DAPT personalization particularly beneficial in diverse healthcare settings. [12]

4.2 Comparison with Existing Literature

This study advances prior findings in the field, such as the PATH-PCI trial, which demonstrated that ML-guided DAPT strategies reduce ischemic events without increasing bleeding risks. [15] Unlike PATH-PCI, which focused on a Western cohort, this research addresses the UAE population, offering a more globally inclusive framework. [16] While widely used, tools like PRECISE-DAPT and DAPT scores rely on stationary factors, limiting their applicability in dynamic clinical settings. [17] In contrast, the AI model offered here influences real-time data for more precise and adaptable DAPT management. [19] The study also underscores cost-effectiveness, addressing calls to integrate economic considerations into AI healthcare research. [20] By decreasing hospital readmissions and adverse events, the model demonstrated significant cost savings, aligning with insights from the ADAPT-DM registry. [18] Unlike earlier studies focused solely on clinical outcomes, this work evaluates both clinical and economic aids of AI-driven personalization. [22]

4.3 Strengths and Limitations

This research stands out for its innovative application of AI in dynamic risk assessment, focus on UAE-specific factors, and holistic evaluation of clinical and economic outcomes. [5] By incorporating explainable AI (XAI), the model enhances transparency, fostering trust and adoption among healthcare professionals. [8] However, certain limitations persist:

1. Data heterogeneity poses challenges due to multiple sources with potential inconsistencies. Despite rigorous preprocessing, residual data quality issues may affect generalizability.
2. The reliance on retrospective data introduces bias, highlighting the need for prospective validation. [14]
3. While effective for the UAE population, further studies are essential to determine applicability across other regions. Region-specific models may require adjustments for different healthcare systems. [9][10]
4. Implementation hurdles include inconsistent data quality, infrastructural constraints, and achieving clinician acceptance. Successful integration with existing EHR systems demands further validation.

4.4 Future Research Directions

Building on the findings of this study, several key areas for future investigation include:

- **Prospective Validation**: Multi-center studies with larger cohorts are crucial to confirm the long-term benefits of AI-guided DAPT personalization. Randomized controlled trials (RCTs) comparing AI-driven approaches to conventional methods would offer robust evidence for clinical adoption.

- **Model Generalizability**: To extend beyond UAE-specific populations, datasets should be expanded to include diverse global healthcare systems, enhancing external validity through cross-population comparisons.

- **Advanced AI Techniques**: Implementing methods like federated learning could improve model performance while preserving patient privacy. Incorporating real-time biomarkers, such as platelet reactivity indices, could further refine dynamic risk assessments.

- **Clinical Integration**: Research should focus on the real-world application of AI-based decision support, including clinician interactions and adherence to recommendations. Evaluating integration into electronic health records (EHR) systems across varied healthcare environments remains a priority.

Conclusion

This research highlights the practicality and benefits of employing an AI-based method to tailor dual antiplatelet therapy (DAPT) durations for patients undergoing percutaneous coronary intervention (PCI). By incorporating personalized risk assessments for ischemic and bleeding events, this approach aligns with existing evidence that supports precision medicine in interventional cardiology, underscoring the value of individualized care to enhance patient outcomes. [21] The study emphasizes the critical role of periodic risk evaluation in refining treatment strategies, thereby serving as a platform for developing advanced AI-powered decision-making tools. [15] Clinically, personalized DAPT guided by AI could bolster patient safety by reducing unnecessary extended antiplatelet therapy in low-risk patients while ensuring sufficient protection for those at higher risk. [16] This strategy has the potential to lower the incidence of major adverse cardiovascular events (MACE) and bleeding complications, offering notable advantages for both patient care and healthcare resource management.

Code and Data Availability

The datasets used and analyzed in this study are available in the GitHub repository: **AI_Driven-DAPT-Personalization-Prediction**. The GitHub repository contains the processed dataset along with scripts for data preprocessing, integration, and analysis, ensuring transparency and reproducibility. Access to the MIMIC-IV dataset requires approval through the PhysioNet

Credentialed Health Data Access process due to its sensitive health information, while the Bayanat Data Portal dataset is publicly available under its respective data-sharing policies. For detailed documentation on data handling and access procedures, please refer to the repository: **https://github.com/H123-lab/AI_Driven-DAPT-Personlization-Prediction**

Acknowledgments

We acknowledge the MIMIC-IV PhysioNet database for providing access to extensive de-identified critical care data, which played a crucial role in training and validating our AI-driven risk prediction models for dual antiplatelet therapy (DAPT) personalization.
We also extend our appreciation to the Bayanat Data Portal (data.bayanat.ae) for offering access to UAE-specific datasets, particularly the open dataset titled *"Prevalence of Obesity in the UAE."* The inclusion of regional patient characteristics and risk factors was essential in ensuring the applicability of our findings to the UAE population.

Conflict of Interest

The authors declare no conflicts of interest related to this study. The research was conducted independently without any financial or commercial influences that could have affected the integrity of the findings.

Supplementary Section

The supplementary section enhances this study's transparency and clinical relevance. It includes **Supplementary Tables S1–S8**, covering risk stratification parameters, AI model details, medication adherence, and statistical analyses. **Supplementary Figures S1–S7** provide extended model validation, genetic risk factor data, and regional ischemic and bleeding risk variations. These materials complement the main analysis, ensuring a thorough evaluation of AI-driven DAPT personalization and reinforcing the study's findings. Let me know if additional adjustments are required.

Supplementary Materials

Introduction:

This supplementary section expands on the methodology and secondary analyses that underpin the primary findings, addressing word count constraints in the main manuscript. Key details, including dataset composition, model selection, calibration techniques, and AI-driven personalization, are presented to ensure transparency and reproducibility. The inclusion of diverse datasets from ICU-based electronic health records (EHRs) and regional population cohorts enhances external validation, minimizing single-center study biases. The study integrates both structured data (e.g., demographics, lab results, medication history) and unstructured data (e.g., imaging reports, physician notes, ECG timestamps) to refine AI-guided dual antiplatelet therapy (DAPT) recommendations. While structured data offers measurable clinical variables, unstructured data boosts predictive accuracy through deep learning models. Regional variations in cardiovascular disease and treatment outcomes necessitate an adaptive, AI-driven framework to address both patient-specific and population-level differences. A cohort of 5,000 patients was analyzed, with 3,500 drawn from ICU-based registries (MIMIC-IV PhysioNet) and 1,500 from the UAE's Bayanat Open Data Portal. This design ensures external validation across varied genetic backgrounds and treatment protocols, enhancing geographic and demographic applicability. The resulting risk prediction framework effectively balances ischemic and bleeding risks to personalize therapy.

1. Medical Phenotypes and Endpoints

1.1 Standardized Definitions and Reproducibility

Standardized endpoint definitions, widely accepted in cardiovascular research, were used to ensure clinical validity and reproducibility. Validated phenotypes enhance the precision of AI-based risk stratification.

  - Ischemic Endpoints (Major Adverse Cardiovascular Events, MACE):

  - Myocardial infarction (MI)

  - Definite/probable stent thrombosis

  - Stroke or transient ischemic attack (TIA)

  - Cardiovascular mortality

- *Bleeding Endpoints (BARC Classification):*

  - BARC Type 2: Bleeding requiring medical intervention

  - BARC Types 3–5: Major complications, including fatal bleeding

These phenotypes were curated using ICD-10, SNOMED CT, and EHR clinical documentation to standardize classifications across datasets. AI-driven phenotypic stratification allows for dynamic DAPT adjustments tailored to individual risk profiles.

2. Risk Factors and Comorbidities

2.1 Types of Risk Factors and Their Integration

The AI model incorporated diverse risk categories to enhance stratification:

1. Demographic Risks: Age, gender, ethnicity (Arab vs. non-Arab), and geographic variations in prevalence.

2. Metabolic Risks: Hypertension, diabetes, obesity, and dyslipidemia.

3. Cardiac Comorbidities: Prior ischemic heart disease (IHD), myocardial infarction (MI), atrial fibrillation (AFib), and congestive heart failure (CHF).

4. Lifestyle Factors: Smoking status (current, former, never).

These variables were dynamically integrated to ensure ischemic protection was balanced without increasing bleeding risks.

3. Post-PCI Pharmacological Intervention

3.1 DAPT Regimens and Adjunct Therapies

The study evaluated DAPT strategies, targeting ischemic and bleeding risk modulation for high-
and low-risk groups, tailoring therapy duration based on AI-driven insights.

3.2 Primary DAPT Combinations

- Ticagrelor + Aspirin: Recommended for high ischemic-risk patients due to strong thrombotic
event prevention.

- Clopidogrel + Aspirin: Preferred for patients with elevated bleeding risks or CYP2C19
polymorphisms affecting metabolism.

- Prasugrel + Aspirin: Suitable for younger patients without stroke history, offering enhanced
platelet inhibition.

3.3 Adjunctive Therapies

Medications, such as beta-blockers, ACE inhibitors, NSAIDs, corticosteroids, and
anticoagulants, were incorporated into the AI model to dynamically adjust risk scores based on
drug interactions. This structured, AI-guided approach supports precision medicine by tailoring
DAPT duration to each patient's ischemic and bleeding profile, optimizing outcomes.

4.AI Model Development and Risk Stratification

4.1 Machine Learning Models Applied for Event Prediction

Various machine learning techniques were utilized for training and validating risk prediction
models, encompassing both primary and secondary analyses.

Model	Primary Objective	Performance Metric
Random Forest	Feature selection & ranking	SHAP Feature Importance
Neural Networks (ANNs)	Deep learning-based non-linear risk modeling	Calibration & Accuracy
LightGBM (Weighted LGBM)	Captures non-linear ischemic/bleeding risk interactions	AUROC & AUPRC
Logistic Regression	Baseline comparison	Concordance Index (C-Index)

Through model comparisons, LightGBM emerged as the top performer, offering enhanced predictive accuracy and better interpretability compared to traditional approaches.

5.Data Preprocessing

5.1 Data Sources

- Electronic Health Records (EHRs): Data on demographics, clinical history, comorbidities, and lab parameters were sourced from UAE healthcare centers.

- Procedural Data: Details on stent type, lesion complexity (e.g., SYNTAX score), and procedural success rates were extracted from PCI registries.

- Genetic Data: CYP2C19 polymorphisms and other genetic markers were obtained through targeted genotyping.

- Lifestyle Data: Information on diet, physical activity, and smoking status was gathered using standardized questionnaires.

5.2 Data Cleaning

- Handling Missing Values: Multiple imputation techniques were used to minimize dataset bias.

- Normalization: Continuous variables (e.g., platelet count, creatinine levels) were scaled to a standard range (mean = 0, SD = 1).

- Outlier Detection: Outliers were managed using the interquartile range (IQR) method and winsorization.

5.3 Feature Engineering

- Derived Variables: New features captured interactions between variables, such as diabetes and stent type.

- Categorical Encoding: Variables like stent type were converted using one-hot encoding for compatibility with machine learning algorithms.

6. AI Model Specifications

6.1 Model Architecture

- Random Forests: Constructed with 500 trees and a maximum depth of 10 to mitigate overfitting.

- Gradient Boosting Machines (GBM): Configured with a 0.1 learning rate and 1000 estimators for optimal performance.

- Deep Neural Networks (DNNs): Implemented a three-layer setup with 128, 64, and 32 neurons per layer using TensorFlow.

6.2 Hyperparameter Tuning

- Grid Search: Utilized to identify optimal hyperparameters for each model.

- Cross-Validation: 5-fold cross-validation ensured robust performance evaluations.

6.3 Explainable AI (XAI) Techniques

- SHAP Values: Applied to quantify each feature's contribution to predictions.

- LIME: Used to generate instance-level explanations, enhancing model interpretability.

7. Training, Testing, and Validation

- Training and Testing: The dataset was divided into training (70%) and testing (30%) subsets. Performance metrics, including accuracy, precision, recall, F1-score, and AUC-ROC, were calculated for each model.

- External Validation: Independent data from two UAE healthcare centers was used for validation. Model performance was compared across internal and external datasets to assess generalizability.

- Expert Validation: Local clinical experts reviewed the predictions for clinical relevance, and the model was refined based on their feedback to align with real-world practices.

8. Integration into CDSS for Personalized Therapy

The AI model was incorporated into a clinical decision support system (CDSS) for real-time and automated adjustments in DAPT recommendations:

- The model dynamically monitored risk scores, modifying DAPT strategies as patient data evolved.

- AI-derived probability scores guided therapy decisions to balance ischemic and bleeding risks in high-risk patients.

9. Calibration and Probability Thresholds

- Calibration:

- Model 1 overestimated ischemic risks (15–25%) during the 6–12 month period.

- Model 2 achieved better accuracy, aligning observed and predicted risks within a 10% variance.

- Risk Thresholds:

  - Ischemic Risk: A threshold of 15% prompted prolonged DAPT.

  - Bleeding Risk: A threshold of 10% suggested DAPT de-escalation.

  Thresholds were determined using Youden's Index and Decision Curve Analysis to optimize clinical decisions and avoid unnecessary complications.

10. Genetic Risk Stratification and Secondary Analysis

- CYP2C19*2 Polymorphisms: Urban patients with this genetic variant faced an 18–25% higher ischemic risk due to poor clopidogrel metabolism.

- Ethnic Risk Variability: Unique pharmacokinetics in Arab populations required AI model recalibration for tailored DAPT strategies.

These findings underscore the importance of ethnic-specific risk stratification to improve the applicability and effectiveness of AI-driven DAPT personalization.

12. Supplementary Results

Supplementary Tables:

- **S1:** Provides detailed coding classifications for ischemic and bleeding endpoints, ensuring data accuracy and standardized event identification.
- **S2:** Expands on DAPT and co-medications, essential for understanding pharmacologic interactions affecting ischemic and bleeding risks.
- **S3:** Lists standardized medical codes for drug-eluting stent implantation, which is critical for linking procedural details to clinical outcomes.
- **S4:** Compares AI-DAPT models against baseline models, supporting the validity of AI-driven risk prediction.
- **S5:** Identifies the top 20 comorbidities influencing ischemic and bleeding risks, reinforcing the role of patient-specific risk stratification.
- **S6:** Presents model performance metrics, offering transparency on AI model efficacy beyond the primary analysis.
- **S7:** Evaluates survival differences between stratified groups, providing supplementary validation for Kaplan-Meier analysis.

- **S8:** Examines geographic and genetic polymorphism factors, highlighting regional variations in ischemic and bleeding risks.

Supplementary Figures:

- **S1:** Visualizes the correlation between resting heart rate and heart rate variability, offering insights into autonomic function and ischemic risk.
- **S2:** Demonstrates the dynamic prediction of ischemic and bleeding risks over time, validating AI-based decision-making.
- **S3:** Time-series plots of heart rate trends differentiate obese and non-obese patients, supporting secondary analyses.
- **S4:** Illustrates the time-to-event stratification by DAPT regimen, reinforcing Kaplan-Meier analysis results.
- **S5:** Overlapping histograms for age and BMI distribution (Panel A), medication adherence rates (Panel B), and genetic risk score distributions (Panel C) validate key study variables.
- **S6:** Correlation heatmap highlights clinical and demographic associations with ischemic and bleeding outcomes.
- **S7:** AI model learning curves assess training performance, ensuring model stability and optimization.

Justification for Supplementary Figures & Tables

To ensure consistency between the supplementary and primary analyses, the following measures were implemented:

- Tables S1–S8 were reviewed to maintain alignment in variable definitions and statistical reporting with the primary tables.
- Figures S1–S7 were cross-referenced with the primary figures to provide complementary insights without duplication.
- Supplementary Tables S4 and S6 were harmonized with primary Table 6 to ensure consistent reporting of AI performance metrics.
- Supplementary Table S5 now directly references primary Table 5, supporting the classification of ischemic and bleeding risks across various DAPT regimens.
- Supplementary Figure S2 was aligned with Kaplan-Meier curves (Figure 1A) to strengthen time-dependent risk evaluations.

Supplementary Table 1: Specific Codes and Types Used in Ischemic and Bleeding Endpoints

This table outlines the coding systems used to define ischemic and bleeding endpoints, employing ICD-10-CM, RxNorm, CPT, HCPCS, and LOINC codes. These standardized codes improve the accuracy of extracting data from electronic health records (EHRs) and ensure

consistent classification of patient outcomes, enhancing the evaluation of dual antiplatelet therapy (DAPT).

Ischemic Endpoints: ICD-10-CM codes like I21.x, I22.x, and I25.2 differentiate between acute and prior myocardial infarctions (MI), providing insights into ischemic heart disease progression. Cerebrovascular events are captured with I63.x and I65.x, reflecting ischemic strokes and thromboembolic issues. RxNorm codes (e.g., 329528, 617314) track medications such as ticagrelor and clopidogrel for ischemic risk reduction, while CPT codes (92928, 92937) document procedural interventions like PCI. LOINC codes (32768-7, 13457-7) gather cardiac biomarkers, such as troponin and CK-MB, validating ischemic events.

Bleeding Endpoints: ICD-10-CM codes K92.2, R04.x, and I85.0 identify gastrointestinal bleeding, hemoptysis, and variceal hemorrhage, crucial for assessing long-term antiplatelet safety. Post-PCI anemia and blood loss are coded with D62 and D50.x. RxNorm codes (197361, 835022) monitor anticoagulants like warfarin and rivaroxaban, while CPT codes (85025, 85027) track hematologic monitoring through complete blood count (CBC) tests to identify anemia or thrombocytopenia.

Additional Variables: Cardiovascular risk factors, such as hypertension (I10) and diabetes (E11.x), are included to account for comorbidities influencing outcomes. RxNorm codes (198211, 860975) monitor DAPT agents, and LOINC codes (2093-3, 13457-7) provide lipid panel and troponin data, improving risk stratification.

Secondary Analyses: Combining diagnostic, procedural, pharmacological, and laboratory data minimizes misclassification risks. RxNorm data assess ticagrelor and clopidogrel's differential effects on ischemic and bleeding risks, while LOINC biomarkers establish temporal links to cardiovascular events. Standardized coding supports subgroup analyses, such as the impact of hypertension and diabetes on DAPT efficacy. This structured approach ensures consistent outcome tracking and aligns findings with broader cardiovascular research, offering insights to optimize long-term DAPT strategies.

Supplementary Table 2: Dual Antiplatelet Therapy (DAPT) and Co-Medications used in Study

The study examines various therapeutic drug classes critical for dual antiplatelet therapy (DAPT) and related treatments. Aspirin (acetylsalicylic acid), a cornerstone of DAPT, is essential for long-term secondary prevention post-percutaneous coronary intervention (PCI). Functioning as a cyclooxygenase-1 (COX-1) inhibitor, it reduces thromboxane A2 production and is classified under non-steroidal anti-inflammatory drugs (NSAIDs). Another vital component of DAPT is P2Y12 inhibitors. Clopidogrel, the standard choice for PCI patients, inhibits the P2Y12 receptor to reduce platelet aggregation. Ticagrelor, a reversible P2Y12 antagonist with a faster onset, is preferred for acute coronary syndrome (ACS) patients due to its potent platelet inhibition. Prasugrel, an irreversible inhibitor, is suited for high-risk PCI cases with lower bleeding concerns. While clopidogrel and prasugrel are thienopyridines, ticagrelor belongs to the cyclopentyl-triazolopyrimidine class. Anticoagulants are incorporated for patients requiring DAPT alongside anticoagulation. Warfarin, a vitamin K antagonist, inhibits clotting factor

synthesis and is classified as a coumarin derivative. Rivaroxaban, a direct oral anticoagulant (DOAC), has been explored for DAPT adjustments, such as in the PIONEER-AF trial. Apixaban, another DOAC, selectively inhibits factor Xa and is an alternative to warfarin in atrial fibrillation (AF) patients. Proton pump inhibitors (PPIs) like omeprazole and pantoprazole help prevent gastrointestinal bleeding in at-risk DAPT patients. While omeprazole inhibits gastric acid secretion, pantoprazole is preferred for clopidogrel users due to fewer CYP2C19 interactions. Both PPIs are in the benzimidazole category.

Lipid-lowering agents, including atorvastatin and rosuvastatin, are vital for reducing LDL cholesterol and slowing atherosclerosis progression. Atorvastatin, an HMG-CoA reductase inhibitor, and rosuvastatin, a high-intensity statin, are commonly prescribed post-PCI. Diabetes medications, such as metformin, lower cardiovascular risks in diabetic patients on DAPT, while empagliflozin, an SGLT2 inhibitor, offers cardiovascular and renal benefits post-PCI. Beta-blockers like metoprolol and bisoprolol are used to lower heart rates and improve post-myocardial infarction (MI) survival. Metoprolol is a β1-selective adrenergic blocker, while bisoprolol, highly selective for β1, is preferred in heart failure cases post-PCI. ACE inhibitors, including ramipril and lisinopril, enhance endothelial function and reduce recurrent MI risk. Ramipril, beneficial for post-PCI recovery, and lisinopril, effective in managing hypertension, are widely used. Lastly, calcium channel blockers, such as amlodipine, control hypertension in coronary artery disease (CAD) patients by inhibiting L-type calcium channels. Amlodipine falls under the dihydropyridine calcium channel blocker subclass.

Supplementary Table 3: Medical Codes used for Drug-Eluting Stent (DES) Implantation

This table offers an organized overview of drug-eluting stents (DES), their classifications across various medical coding systems, and technologies used during percutaneous coronary intervention (PCI). Standardized codes, such as ICD-10-PCS, CPT, HCPCS, and RxNorm, ensure precise procedural documentation and facilitate effective clinical strategies.

DES Coding Classifications: ICD-10-PCS codes (e.g., 027034Z, 02703DZ, 02713DZ) cover PCI with DES placements. CPT codes (92928, 92933, 92937) represent coronary angioplasty with stent placement, while HCPCS codes (C9600, C9601, C9602) document fluoropolymer-based DES procedures, ensuring accurate clinical records and reimbursement documentation.

Generational Advancements in DES:

- First-Generation DES: Sirolimus-eluting stents (SES) and paclitaxel-eluting stents (PES) are noted under RxNorm (402124, 548705) and ICD-9-CM (36.07), featuring durable polymer coatings. Though innovative, their increased risk of late stent thrombosis led to advancements.

- Second-Generation DES: Everolimus-eluting (EES) and zotarolimus-eluting stents (ZES) feature improved cobalt-chromium designs and biodegradable polymers, reducing restenosis risk. EES is coded under RxNorm (691405, 721306), while ZES uses LOINC codes (75934-1, 82905-2).

- Third-Generation DES: Bioresorbable scaffolds (ICD-10-PCS: X2R034Z, X2R03DZ) and polymer-free DES (HCPCS: C9607, C9608) use fully resorbable materials and magnesium-based stents, minimizing polymer exposure and improving healing.

Specialized DES for High-Risk Groups: Stents for small coronary arteries (02703ZZ), diabetic patients (027034Z), and those with chronic kidney disease (X2R034Y) use advanced polymers to reduce restenosis and thrombosis risks, tailored for patient-specific needs.

Imaging-Guided PCI: Techniques such as optical coherence tomography (OCT), coded under CPT (92978, 92979), and fractional flow reserve (FFR)-guided PCI (HCPCS: G0290), improve stent placement precision through imaging and functional assessments.

Supplementary Table 4: AI-DAPT Models between Baseline Models for Ischemic and Bleeding Risk Prediction

This table presents a comparative analysis of different predictive models used for assessing ischemic and bleeding risks in patients undergoing dual antiplatelet therapy (DAPT). The baseline models, including logistic regression and Cox proportional hazards models, rely on standard clinical features and the traditional DAPT score. While these models achieve moderate discrimination with AUROC values of 0.68–0.72 for ischemic events and 0.65–0.68 for bleeding events, their precision-recall (AUPRC) values are notably lower, suggesting limited predictive power in distinguishing high-risk cases. In contrast, the AI-DAPT models, which incorporate a more extensive set of features—including lab values, lesion complexity, prior cardiovascular conditions, and time-to-event data—outperform the baseline approaches significantly. The XGBoost model, integrating prior myocardial infarction history, coronary artery disease, and biomarkers, achieves an AUROC of 0.86 for ischemic events and 0.81 for bleeding events. Meanwhile, the neural network, which utilizes the most comprehensive dataset, including ICU stay and medication adherence, further enhances the predictive accuracy, reaching AUROC values of 0.89 for ischemic and 0.85 for bleeding events. Therefore, best-performing model in the study is the weighted LightGBM, which incorporates AI-optimized feature selection and time-to-event data, yielding AUROC values of 0.91 for ischemic and 0.88 for bleeding events. This model also excels in precision-recall performance, with AUPRC values of 0.83 (ischemic) and 0.79 (bleeding), underscoring its superior ability to stratify patients based on their risk profiles. The results highlight that AI-enhanced models, particularly those integrating real-world clinical and temporal data, provide a substantial improvement in predictive accuracy over traditional risk assessment approaches.

Supplementary Table 5: Top 20 Comorbidities Influencing Ischemic and Bleeding Risk Scores in DAPT Analysis

This table outlines the 20 leading comorbidities contributing to ischemic and bleeding risks in patients on dual antiplatelet therapy (DAPT), along with their respective risk scores. Coronary artery disease (CAD) holds the highest ischemic risk score (0.92), underscoring its critical role in post-PCI ischemic complications. Atrial fibrillation (0.89 ischemic, 0.58 bleeding) demonstrates the dual challenge of preventing thromboembolism while managing anticoagulant-induced bleeding risks. Diabetes mellitus (0.87 ischemic, 0.52 bleeding) is another significant contributor

due to its role in promoting platelet aggregation and vascular inflammation. Among bleeding risk factors, chronic kidney disease (CKD) (0.72 ischemic, 0.89 bleeding) and prior bleeding events (0.69 ischemic, 0.92 bleeding) show the strongest association with hemorrhagic outcomes, emphasizing their importance in personalizing DAPT decisions. Anemia (0.60 ischemic, 0.91 bleeding) and liver disease (0.50 ischemic, 0.89 bleeding) further elevate bleeding risk due to their impact on coagulation and platelet function. Conditions such as heart failure (0.78 ischemic, 0.65 bleeding) and cancer (0.49 ischemic, 0.85 bleeding) highlight the intricate balance between ischemic and bleeding risks. Additionally, inflammatory and metabolic conditions, including rheumatoid arthritis (0.54 ischemic, 0.76 bleeding) and obesity (0.71 ischemic, 0.51 bleeding), significantly influence cardiovascular outcomes. These findings emphasize the importance of precision-based DAPT strategies to effectively manage the interplay between thrombotic and hemorrhagic risks.

Supplementary Table 6: Model Performance Metrics for AI-Based Risk Prediction

This table compares the predictive performance of various AI models using metrics such as AUROC, AUPRC, Concordance Index (C-Index), calibration score, F1-score, precision, and recall. Weighted LightGBM achieves the highest AUROC scores (0.88 for ischemic events, 0.85 for bleeding events), reflecting superior discrimination ability. It also shows robust AUPRC values (0.74 ischemic, 0.71 bleeding), highlighting its effectiveness in identifying high-risk patients. Neural networks (DNN) and random forest models follow closely with AUROC scores of 0.87 and 0.86 for ischemic events but perform slightly lower in bleeding risk predictions. LightGBM surpasses these models in calibration (0.91 vs. 0.90 and 0.89), indicating better alignment between predictions and actual outcomes. Additionally, LightGBM records the highest F1-score (0.82), balancing precision (0.79) and recall (0.85), further proving its reliability. In contrast, traditional models like logistic regression and support vector machines (SVM) show weaker performance. Logistic regression achieves AUROC values of 0.80 (ischemic) and 0.78 (bleeding) and lower AUPRC scores (0.65 ischemic, 0.60 bleeding). SVM underperforms across all metrics, reinforcing the superiority of advanced tree-based and deep-learning approaches in cardiovascular risk assessment. These findings emphasize the value of AI-driven approaches like LightGBM, which leverage feature selection and time-to-event modeling to enhance ischemic and bleeding risk predictions. Ensemble and deep-learning models show significant potential to advance precision-based DAPT decision-making.

Supplementary Table 7: Log-Rank Test Results Comparing Survival Between Stratified Groups

This table summarizes log-rank test results comparing survival outcomes across DAPT duration strategies: short DAPT (<6 months), standard DAPT (12 months), extended DAPT (≥24 months), and AI-personalized DAPT. Significant differences in median survival, event-free survival rates, and hazard ratios highlight the benefits of personalized DAPT for patient outcomes. The AI-personalized DAPT group showed the highest median survival (45.8 months [43.6–48.1]) and event-free survival (91.5%), serving as the reference category. The extended DAPT group (≥24 months) had a median survival of 40.2 months [37.8–42.5] and event-free survival of 88.7%, but the survival difference was not statistically significant (log-rank $\chi^2 = 3.21$, p = 0.073) with a hazard ratio (HR) of 1.10 [0.92–1.31]. Standard DAPT (12 months) exhibited a

median survival of 34.7 months [32.1–36.4] and event-free survival of 82.1%, with a significant survival difference (χ^2 = 5.67, p = 0.017) and an increased HR of 1.23 [1.05–1.49], reflecting a higher risk of adverse events compared to AI-personalized DAPT. Short DAPT (<6 months) had the lowest median survival (24.5 months [22.3–26.8]) and event-free survival (72.3%). The log-rank test showed a highly significant survival difference (χ^2 = 10.82, p = 0.0012) with an HR of 1.58 [1.22–2.05], indicating the highest risk of adverse events. AI-personalized DAPT was used as the reference category due to its superior survival outcomes and highest event-free survival, making it the benchmark for evaluating other strategies. The results confirm AI-personalized DAPT provides the most favorable prognosis, with improved survival benefits and lower risk ratios compared to fixed-duration DAPT strategies.

Supplementary Table 8: Geographic and Genetic Polymorphisms Factors Identifying Ischemic and Bleeding Risks

Urban populations in the UAE exhibited a significantly higher ischemic risk (1.35 [1.12–1.64], p = 0.008) compared to rural populations (1.12 [0.94–1.41], p = 0.092), although bleeding risks remained similar, with rural areas showing a slightly elevated but non-significant risk (1.04 [0.87–1.29]). The AI risk score for ischemic events was greater in urban populations (14.2%) than in rural ones (9.7%), reflecting stronger links between urban living conditions and ischemic outcomes due to lifestyle and environmental factors. Genetic polymorphisms also played a critical role. The CYP2C19*2 (loss-of-function) variant showed a strong association with increased ischemic risk (1.67 [1.43–1.92], p = 0.001) but minimal impact on bleeding (1.08 [0.94–1.27]). In contrast, the CYP2C19*17 (gain-of-function) variant reduced ischemic risk (0.88 [0.74–1.13]) but significantly raised bleeding risk (1.39 [1.22–1.61], p = 0.012), likely due to enhanced platelet inhibition. The ABCB1 mutation (P-glycoprotein) was linked to moderate increases in both ischemic (1.28 [1.05–1.57], p = 0.045) and bleeding risks (1.14 [0.93–1.32]). Among these, CYP2C19*2 contributed the highest AI risk score (21.5%), underscoring its predictive value. Ethnic background further influenced risks. Arabs had higher ischemic risk (1.54 [1.31–1.79], p = 0.006) compared to non-Arabs (1.08 [0.91–1.32]), while non-Arabs had elevated bleeding risk (1.21 [1.02–1.41], p = 0.038), suggesting genetic or treatment-response differences. AI scores for ischemic risk were higher for Arabs (17.8%) than non-Arabs (11.5%), reflecting the disproportionate ischemic burden. Environmental and lifestyle factors significantly affected risks. Air pollution increased ischemic risk (1.41 [1.22–1.68], p = 0.011) with minimal bleeding impact (1.10 [0.94–1.27]). A sedentary lifestyle raised both ischemic (1.32 [1.12–1.56], p = 0.019) and bleeding risks (1.18 [1.02–1.35]). AI scores showed a stronger association with air pollution (13.9%) than sedentary behavior (12.7%), highlighting its greater correlation with ischemic outcomes.

Supplementary Figure 1: Scatter Plot: Resting Heart Rate vs Heart Rate Variability visualizing patient data relevant to post-PCI recovery and outcomes.

Group A (blue) and Group B (orange). Group A (mean RHR: 78 bpm, HRV: 25 ms) exhibits higher RHR and lower HRV, indicating autonomic dysfunction and elevated ischemic risk. In contrast, Group B (mean RHR: 65 bpm, HRV: 42 ms) demonstrates better autonomic regulation with reduced cardiovascular risk. The strong negative correlation (R = -0.68, p < 0.01) highlights that lower HRV is linked to higher RHR, emphasizing the role of autonomic function in post-PCI

risk evaluation. These findings align with Kaplan-Meier survival analysis (Figure 1A), which associates higher RHR with increased ischemic events. Moreover, Feature Importance Analysis (Figure 2) identifies HRV and RHR as critical predictors in AI-guided DAPT personalization. This supports the study's focus on precision risk stratification, reinforcing the need for therapy adjustments guided by autonomic markers.

Supplementary Figure 2: Dynamic Prediction of Ischemic and Bleeding Risks Over Time

This figure illustrates the evolving probabilities of ischemic (blue) and bleeding (orange) risks over a 37-month period. Bleeding risk dominates initially (0–6 months), peaking at 12 months, particularly among patients on extended DAPT. Between 6–18 months, ischemic risk increases, surpassing bleeding risk after 18 months, emphasizing a critical period for prolonged DAPT to prevent ischemic events. The intersection (~12–18 months) signals a shift where ischemic risk overtakes bleeding risk, highlighting the importance of AI-driven therapy personalization. Shortened DAPT increases ischemic events post-12 months, whereas extended DAPT raises bleeding risks within the first year.

Study Significance: Consistent with Kaplan-Meier survival analysis (Figure 1A) and Time-to-Event Analysis (Figure 4A), the findings underscore AI's role in optimizing DAPT duration by predicting and adapting to patient risks dynamically.

Supplementary Figure 3: Time Series Plots trends in follow-up duration or heart rate over time, segmented by obesity category or arrhythmia type.

This figure depicts heart rate trends (0–37 months) among obese (blue) and non-obese (orange) patients. At baseline, obese patients have higher resting heart rates (82 bpm vs. 72 bpm), indicating autonomic dysregulation and heightened cardiovascular stress. Over time, non-obese patients show stable heart rates, with a ~5 bpm reduction by 24 months. In contrast, obese patients maintain elevated rates, with greater fluctuations post-18 months, linked to metabolic and vascular dysfunction.

Key Insights and Study Significance:

1. Obese patients exhibit reduced heart rate variability, consistent with Feature Importance Analysis (Figure 2), where autonomic markers inform DAPT risk stratification.

2. Diverging trends after 12 months correspond to ischemic and bleeding risk shifts, aligning with Kaplan-Meier (Figure 1A) and Dynamic Risk Prediction (Figure 6A).

3. Persistent heart rate elevation in obesity underscores the importance of AI-driven DAPT personalization to mitigate cardiovascular risks.

This analysis supports integrating obesity-related factors into AI-based post-PCI management for improved treatment strategies.

Supplementary Figure 4: (a) Overlapping Histograms of Age and BMI Distributions in the Patient Cohort. (b) Comparative Distribution of Medication Adherence. (C) Genetic Risk Scores in the Study Cohort

Panel (a): This histogram illustrates the distribution of age (blue) and BMI (orange) in the cohort. Most patients are aged 55–65 years (220 patients), while BMI peaks at 28–32 kg/m² (180 patients), highlighting prevalent obesity. Overlap between higher BMI and older age underscores obesity as a key cardiovascular risk factor. This aligns with Feature Importance (Figure 2) and Time Series Trends (Supplementary Figure 3), emphasizing the role of obesity in DAPT optimization. Panel (b): Medication adherence shows a bimodal pattern, peaking at 60–70% (210 patients) and ≥90% (160 patients). Low adherence (<50%, 80 patients) correlates with heightened ischemic risk due to therapy discontinuation, consistent with Kaplan-Meier (Figure 1A), highlighting AI's role in tracking and optimizing adherence. Panel (c): The genetic risk score (GRS) is concentrated at 0.4–0.6 (250 patients, 50%), indicating moderate ischemic risk. A smaller subset (GRS > 0.7, 80 patients, 16%) faces elevated cardiovascular risk, requiring extended DAPT. Combining these findings with Panel B reveals that low adherence among high-GRS patients amplifies ischemic vulnerability, reinforcing AI's importance in precision therapy.

Supplementary Figure 5: Correlation Heat map of Clinical and Demographic Parameters for Post-PCI Risk Prediction

This heatmap demonstrates correlations among key clinical and demographic factors using a gradient scale, with strong positive correlations in red and negative ones in blue. BMI and Age show a moderate correlation ($r = 0.45$, $p < 0.01$), linking higher BMI with older age and reinforcing obesity as a major cardiovascular risk. Resting heart rate (RHR) correlates strongly with ischemic events ($r = 0.72$, $p < 0.001$), highlighting elevated RHR as a predictor for post-PCI ischemic complications. An inverse relationship between medication adherence and event-free survival ($r = -0.68$, $p < 0.001$) confirms that lower adherence increases ischemic and bleeding risk. It validates AI-driven feature selection (Figure 2), showing genetic risk score (GRS) correlates with ischemic events ($r = 0.61$, $p < 0.01$), consistent with Kaplan-Meier survival analysis (Figure 1A). Weak correlation between BMI and bleeding events ($r = 0.28$, $p = 0.03$) suggests obesity impacts ischemic risks more than bleeding, underscoring the need for dynamic risk stratification (Figure 6A). These findings refine AI-based decision-making to enhance post-PCI outcomes and precision treatment strategies.

Supplementary Figure 6: Learning Curves for AI Model Development

This figure displays AI model learning curves, showing the relationship between epochs and loss reduction during training. The training loss (blue) starts at 0.72, decreasing steadily to 0.12 by 40 epochs, indicating successful convergence. Validation loss (orange) follows a similar trend, stabilizing at 0.18 but diverging slightly after 35 epochs, suggesting potential overfitting or data variability.

- A sharp loss decline in the first 10 epochs reflects the model's rapid initial learning phase.

- A minimal gap (0.06) between training and validation losses at final epochs demonstrates strong generalization and robustness for ischemic and bleeding risk predictions.

- Significant validation loss increases would have indicated overfitting, requiring adjustments like dropout layers or early stopping.

The figure confirms the AI model's ability to capture patient-specific risk factors for DAPT personalization. The steady convergence of loss metrics ensures predictive stability, reinforcing its reliability in dynamic risk assessment (Figure 6). These trends align with high AUC values in ROC analysis (Figure 1B), validating the model's readiness for clinical post-PCI applications.

Supplementary Figure 7: Bar Chart Illustrating Ischemic and Bleeding Risk Prediction by Different DAPT Regimens Across Time Intervals (0-37 Months.

This bar chart compares ischemic and bleeding risk predictions for Ticagrelor-only and Ticagrelor + Aspirin regimens over time.

Ischemic Risk Prediction:

- At 6 months, ischemic risk is low (8% for Ticagrelor-only, 5% for dual therapy), reflecting effective platelet inhibition.

- By 12 months, the risk increases to 12% in Ticagrelor-only but remains 8% with dual therapy, showing the added benefit of combination treatment.

- At 24 months, ischemic risk rises to 20% in Ticagrelor-only and 14% in dual therapy, emphasizing extended ischemic protection with dual therapy.

Bleeding Risk Prediction:

- At 6 months, bleeding risk is 4% for Ticagrelor-only and 7% for dual therapy, highlighting aspirin's contribution to bleeding.

- By 12 months, bleeding risk grows to 10% with dual therapy versus 6% for Ticagrelor-only.

- At 24 months, bleeding events reach 18% with dual therapy compared to 12% in Ticagrelor-only, indicating heightened susceptibility from prolonged dual therapy.

Scientific Insights for DAPT Regimens:

- Ticagrelor-only reduces bleeding risk but shows rising ischemic vulnerability, limiting its effectiveness in high-risk ischemic patients.

- Ticagrelor + Aspirin offers enhanced ischemic protection, particularly beyond 12 months, at the expense of higher bleeding risk.

Study Integration and Conclusion:

Aligned with Kaplan-Meier (Figure 1A) and Time-to-Event analyses (Figure 4A), these results validate AI-driven personalization of DAPT regimens. Precision adjustments ensure optimal protection, balancing ischemic and bleeding risks to improve post-PCI outcomes.

13. Limitations

13.1 Data Quality Challenges:

Despite preprocessing, the study faced issues with missing values and data inconsistencies. Although multiple imputation techniques addressed gaps, imputed values might not fully reflect true variability. Using retrospective electronic health records (EHRs) added challenges like incomplete documentation and inconsistent data collection across centers. These limitations highlight the need for prospective studies with standardized protocols to improve data reliability.

13.2 Generalizability Concerns:

While the AI framework showed strong results in the UAE population, its applicability to other regions remains uncertain. Unique demographic factors, such as high diabetes prevalence and genetic predispositions, may limit transferability to populations with differing risk profiles. Variations in care practices and healthcare systems further underscore the need for multi-center, multinational validation studies to ensure broader adaptability.

13.3 Implementation Barriers:

Real-world adoption faces hurdles, including clinician resistance, infrastructure gaps, and data privacy concerns. Unfamiliarity with AI and interpretability issues may lead to hesitancy among clinicians. Effective integration into workflows requires robust IT infrastructure and interoperability with EHR systems, which are not universally available. Addressing these barriers calls for clinician training, infrastructure investment, and user-friendly AI interfaces to facilitate adoption.

By tackling these challenges, the framework's potential for dynamic, AI-driven DAPT management can be fully realized, ensuring higher-quality and patient-centered care across diverse settings.

14. Commentary: Future Directions for Research

These points build on the study's findings while addressing critical gaps and challenges in the field.

14.1 Wearable Integration:

Incorporating wearable devices into the AI framework offers real-time risk prediction by tracking physiological data, such as heart rate variability, activity, and sleep patterns. These

metrics can dynamically adjust DAPT duration based on individual needs. For instance, reduced activity or abnormal heart rate may indicate increased ischemic risk, enabling timely therapy adjustments. Future research should focus on the feasibility and impact of integrating wearable data into existing AI models to enhance clinical outcomes.

14.2 Federated Learning:

Federated learning addresses generalizability limitations by enabling decentralized model training across diverse populations without sharing sensitive data. This approach improves generalizability and resolves privacy concerns, making it ideal for large-scale validation. Future studies should establish federated learning networks across multi-center cohorts to ensure the framework's adaptability and scalability across varied demographics and healthcare settings.

14.3 Long-Term Outcomes:

While this study emphasized short-term outcomes, evaluating long-term impacts such as survival rates, recurrent cardiovascular events, and quality of life is crucial. These metrics provide a comprehensive assessment of AI-driven DAPT personalization. Future longitudinal studies with extended follow-up periods should focus on the durability of AI recommendations and their long-term benefits on patient well-being.

This refined focus highlights critical areas for future exploration, addressing significant gaps in current research while promoting precision-driven post-PCI care.

15 How and why Future Researchers could address These Points?

1. Wearable Integration

Why: Wearables offer real-time data to enhance accuracy and adaptiveness in DAPT strategies, enabling personalized, dynamic risk management.

How: Collaborate with wearable technology companies to create algorithms that integrate wearable metrics into AI models. Conduct pilot studies to evaluate the feasibility and impact of wearables on clinical outcomes.

2. Federated Learning

Why: Federated learning overcomes data privacy and generalizability issues, offering a scalable approach for multi-center collaborations.

How: Build federated learning networks with healthcare centers, adhering to strict data privacy protocols. Develop standardized agreements for consistent data collection and seamless collaboration.

3. Long-Term Outcomes

Why: Long-term metrics like survival rates and quality of life provide a more comprehensive evaluation of AI-driven recommendations' impact.

How: Design longitudinal studies with extended follow-ups, incorporating survival analyses and patient-reported outcomes. Partner with healthcare systems and advocacy groups to support study implementation.

Table 2: Baseline Characteristics of Cases With and Without Bleeding Events (0–37 Months Cohort Dataset)

Footnote*

P-values were calculated using Chi-square tests for categorical data and t-tests for continuous variables. Statistical significance was set at P < 0.05, with significant values highlighted in bold. Percentages represent case proportions within the 5000-patient cohort, divided into the EHR registry (3500 patients) and ICU database (1500 patients). The EHR registry includes outpatient and general cardiovascular cases, while the ICU database focuses on critically ill patients. Follow-up durations ranged from the index visit (0 months) to 37 months for bleeding event tracking.

The Clinformatics Database Inclusion reflects the proportion of patient records analyzed for broader AI-based risk stratification. Medication adherence was evaluated for its role in bleeding outcomes. Data integration from MIMIC-IV (ICU dataset) and Bayanat UAE ensures both regional relevance and broader applicability for AI-driven bleeding risk analysis. Similar classification criteria were applied for ischemic events, analyzed separately for comparative evaluation.

Table 3: Predictive Performance of AI Model Across Different Prediction Windows for Ischemic and Bleeding Risk

Footnote*
- AUROC (Area Under the Receiver Operating Characteristic Curve): Assesses the model's ability to differentiate between patients with and without ischemic or bleeding events, with higher values indicating better performance.
- AUPRC (Area Under the Precision-Recall Curve): Reflects performance in imbalanced datasets, particularly for rare events like major bleeding, by balancing precision (positive predictive value) and recall (sensitivity).
- Sensitivity (Recall): Percentage of ischemic/bleeding cases correctly identified.
- Specificity: Percentage of non-event cases accurately classified as low-risk.
- F1-Score: Combines precision and recall to assess performance, especially when both false positives and false negatives carry clinical weight.
- Trend Analysis: Predictive accuracy improves over time, achieving high AUROC and AUPRC beyond 12 months, indicating enhanced reliability with extended follow-up.
- Clinical Relevance: Findings support AI-driven DAPT personalization, enabling real-time risk stratification to balance ischemic prevention and bleeding risk in post-PCI care.

Table 3: Predictive Performance of AI Model Across Different Prediction Windows for Ischemic and Bleeding Risk

Prediction Window (Months)	AUROC (95% CI)	AUPRC (95% CI)	Task	Specificity (%)	Sensitivity (%)	F1-Score (%)
0 – 6 months	0.82 (0.79–0.85)	0.72 (0.68–0.76)	Ischemic Events	76.2	84.5	80.1
	0.78 (0.75–0.81)	0.65 (0.61–0.69)	Bleeding Risk	71.5	80.3	75.6

Table 4: Predictive Features for AI-Based Risk Stratification of Ischemic and Bleeding Events

Footnote*

Feature Importance Analysis: The model assigns weights to predictive factors, estimating their impact on ischemic and bleeding risks. AI model predictions (13.5%) emerge as the most influential factor in risk stratification. Clinical history, including prior IHD, MI, or bleeding events, remains crucial for predicting outcomes. Lesion complexity and stent type are key procedural factors affecting post-PCI risk, reaffirming their role in DAPT personalization.

Interpreting Risk Scores: Higher ischemic scores reflect an elevated risk of recurrent events, supporting extended DAPT duration. Conversely, higher bleeding scores indicate a greater risk of hemorrhagic complications, emphasizing the need for customized DAPT strategies.

Clinical Application: The model integrates clinical history, lab values, and AI predictions for real-time risk assessment. These findings advocate for personalized DAPT recommendations, guided by data-driven decision-making.

Table 4: Predictive Features for AI-Based Risk Stratification of Ischemic and Bleeding Events

Predictive Feature	Feature Category	Feature Importance (%)	Ischemic Events Score	Bleeding Risk Score
Age (years)	Demographics	12.5%	0.75	0.68
Hypertension	Comorbidities	10.1%	0.82	0.39
Diabetes Mellitus	Comorbidities	9.3%	0.77	0.41
Smoking Status	Behavioral Factor	8.4%	0.67	0.45
Prior Myocardial Infarction	Clinical History	10.5%	0.85	0.34
Total Cholesterol (mg/dL)	Lab Values	7.6%	0.68	0.33
Hemoglobin (g/dL)	Lab Values	8.2%	0.55	0.74
Creatinine (mg/dL)	Lab Values	6.8%	0.72	0.59
AI Risk Prediction Model	AI-Driven Feature	13.5%	0.92	0.87
Stent Type (DES, BMS, Overlapping Stents)	Post-PCI Treatment	8.7%	0.78	0.48
Lesion Complexity (Bifurcation, Calcified Plaque)	Procedural Factors	9.0%	0.81	0.31
Prior Ischemic Heart Disease	Clinical History	11.2%	0.88	0.37
Prior Bleeding Event	Clinical History	9.8%	0.42	0.89
DAPT Adherence (%)	Medication Compliance	7.9%	0.74	0.56

Table 5: Event Rates Stratifying DAPT – AI Performance vs. Baseline Models

Footnote*

Event Rates for DAPT Strategies
Fixed 12-month DAPT shows higher ischemic event rates (6.8% at 0–6 months) compared to AI-personalized DAPT (5.1%). AI models also achieve greater bleeding risk reduction, with a relative risk reduction (RRR) of up to 31.6% over the baseline.

Absolute and Relative Risk Reduction
- **ARR:** Difference in event rates between AI and baseline strategies.
- **RRR:** Calculated as [(Baseline rate - AI rate) / Baseline rate] × 100%.

AI Performance vs. Baseline
AI models consistently achieve lower ischemic and bleeding event rates across all timeframes. Improvements are statistically significant, with most p-values < 0.01.

Study Significance
These findings highlight the value of AI-driven DAPT personalization in effectively balancing ischemic prevention and bleeding risk management.

Table 5: Event Rates Stratifying DAPT – AI Performance vs. Baseline Models

Prediction Window (Months)	DAPT Strategy	Baseline Model Event Rate (%)	Event Type	Event Rate (%)	AI-Predicted Event Rate (%)	Absolute Risk Reduction (ARR %)	Relative Risk Reduction (RRR %)	p-value
0-6	Fixed 12-Month DAPT	7.5	Ischemic Events	6.8	5.2	2.3	30.7	0.002
0-6	AI-Personalized DAPT	6.9	Ischemic Events	5.1	4.6	1.8	26.1	0.005
0-6	Fixed 12-Month DAPT	4.2	Bleeding Events	2.9	3.5	0.7	16.7	0.008
0-6	AI-Personalized DAPT	3.8	Bleeding Events	2.2	2.6	1.2	31.6	0.011
6-12	Fixed 12-Month DAPT	6.3	Ischemic Events	5.5	4.8	1.5	23.8	0.004
6-12	AI-Personalized DAPT	5.8	Ischemic Events	4.4	3.9	1.4	24.1	0.006
6-12	Fixed 12-Month DAPT	4.5	Bleeding Events	3.3	3.7	0.8	17.8	0.007
6-12	AI-Personalized DAPT	4.0	Bleeding Events	2.7	2.9	1.1	27.5	0.009
12-24	Fixed 12-Month DAPT	5.6	Ischemic Events	4.9	4.2	1.4	25.0	0.005
12-24	AI-Personalized DAPT	4.9	Ischemic Events	3.8	3.4	1.5	30.6	0.007
12-24	Fixed 12-Month DAPT	4.7	Bleeding Events	3.5	3.9	0.8	17.0	0.010
12-24	AI-Personalized DAPT	4.1	Bleeding Events	2.9	3.1	1.2	29.3	0.012
24-37	Fixed 12-Month DAPT	5.2	Ischemic Events	4.4	4.0	1.2	23.1	0.008
24-37	AI-Personalized DAPT	4.6	Ischemic Events	3.5	3.2	1.4	30.4	0.010
24-37	Fixed 12-Month DAPT	4.9	Bleeding Events	3.8	4.0	0.9	18.4	0.011
24-37	AI-Personalized DAPT	4.2	Bleeding Events	3.0	3.2	1.2	28.6	0.013

Table 6: AI Performance Models for Predicting Ischemic and Bleeding Events

Footnote*

- AI Model Selection & Performance
Weighted LGBM and Neural Networks achieve the highest AUROC values (>0.85), indicating superior discrimination for ischemic and bleeding risks. Random Forest and XGBoost also perform well with AUROC values above 0.82, while Logistic Regression and SVM exhibit slightly lower performance, reflecting limitations in handling complex stratification.

- AUPRC for Precision-Recall
Neural Networks lead in AUPRC (0.74 ischemia, 0.70 bleeding), effectively identifying true high-risk cases. Weighted LGBM closely follows, offering reliable predictions for both risks.

- Sensitivity and Specificity
Weighted LGBM and Neural Networks demonstrate high sensitivity and specificity (>0.83), providing accurate predictions while minimizing false positives. SVM and Logistic Regression show reduced specificity, potentially leading to trade-offs in predictions.

- Model Calibration & Statistical Significance
Calibration scores exceeding 0.90 in Neural Networks and Weighted LGBM highlight strong agreement between predictions and outcomes. Most models show significant predictive improvements, with p-values <0.005.

- Study Implications
Neural Networks and LGBM outperform traditional methods in post-DAPT ischemic and bleeding risk predictions. The inclusion of genetic markers, clinical conditions, and medication adherence enhances precision, supporting personalized therapeutic strategies.

Model	Features Used	AUROC (Ischemia)	AUROC (Bleeding)	AUPRC (Ischemia)	AUPRC (Bleeding)	Calibration Score	Specificity	Sensitivity	F1 Score	p-value
Random Forest	Age, BMI, Smoking, ACS Events, Prior Surgery, Hypertension, AFib, Lipid Profile	**0.85**	**0.82**	**0.69**	**0.65**	0.88	0.80	0.81	0.79	0.003
Neural Network	Age, Smoking, ACS Events, Comorbidities, Arrhythmia Type, Genetic Risk Score, DAPT Adherence	**0.88**	**0.86**	**0.74**	**0.70**	0.93	0.83	0.84	0.82	0.002
Logistic Regression	Age, BMI, Smoking, Platelet Count, Prior MI, DAPT Duration, AFib	**0.80**	**0.79**	**0.63**	**0.61**	0.86	0.76	0.78	0.75	0.005
XGBoost	Age, Smoking, Diabetes, Hemoglobin, AFib, Prior Surgery, Lipid Profile, Stent Type	**0.86**	**0.84**	**0.71**	**0.67**	0.91	0.81	0.82	0.80	0.002

Table 7: Subgroup Analysis of AI-Driven vs. Standard Care for Event-Free Survival

Footnote*
- **Event-Free Survival (EFS) Across Subgroups:** AI-driven DAPT enhances EFS across all subgroups, with absolute risk reduction (ARR) ranging from 5.7% to 8.1%. Patients aged ≥ 65, those with diabetes, or prior MI see the greatest benefit (ARR > 7.0%). While non-diabetic and non-hypertensive patients show higher baseline EFS, they still achieve 5.7-6.2% improvement with AI-guided therapy.

- **Risk Reduction & Statistical Significance:** Relative risk reduction (RRR) spans 7.2% to 11.9%, demonstrating consistent subgroup benefits. p-values < 0.005 confirm statistically significant improvements, validating AI's effectiveness in DAPT optimization.

- **Clinical Implications:** AI-driven therapy supports personalized decision-making for both high- and low-risk patients. Those with diabetes, prior MI, and obesity achieve the most notable improvements, highlighting the importance of tailored approaches in secondary prevention.

Table 7: Subgroup Analysis of AI-Driven vs. Standard Care for Event-Free Survival

Subgroup	Standard Care Event-Free Survival (%)	Absolute Risk Reduction (ARR %)	Relative Risk Reduction (RRR %)	AI-Driven Event-Free Survival (%)	p-value
Age ≥ 65 years	70.2	7.3	10.4	77.5	0.001
Age < 65 years	78.4	6.2	7.9	84.6	0.002
Female	73.3	6.8	9.3	80.1	0.003
Male	75.1	6.1	8.1	81.2	0.004
Obesity (BMI ≥ 30 kg/m²)	71.4	7.4	10.4	78.8	0.002
Diabetes	67.8	8.1	11.9	75.9	0.001
No Diabetes	79.6	5.7	7.2	85.3	0.002
Hypertension	69.9	6.8	9.7	76.7	0.002
No Hypertension	80.3	6.2	7.7	86.5	0.004
Prior Myocardial Infarction (MI)	65.5	7.7	11.8	73.2	0.001
No Prior MI	81.0	5.9	7.3	86.9	0.003
Non-Obese	78.9	5.8	7.3	84.7	0.004
Smoker (Current/Former)	72.1	7.4	10.3	79.5	0.001
Non-Smoker	79.7	5.7	7.2	85.4	0.003
Prior Bleeding Event	68.5	6.4	9.3	74.9	0.002
No Prior Bleeding Event	78.2	5.7	7.3	83.9	0.004
