ABSTRACT

Introduction
Physical function, defined as the ability to perform activities of daily living, is a critical, diagnosis-agnostic contributor to quality of life and healthcare value. This is especially true for older adults who face high rates of mobility limitations and functional decline following hospitalization. Systematically tracking physical function across the continuum of care is essential for monitoring patient recovery, preventing adverse events, and improving care transitions. Despite its importance and the potential for electronic health records (EHRs) to enable this tracking, physical function is not routinely measured. This paper explores the challenges and opportunities of leveraging EHR data to track physical function by presenting a case study of extracting physical function data for patients transitioning from the hospital to home care in a large healthcare system, illustrating barriers and providing recommendations for future work.

Methods
We began by using an expert consensus group to identify data elements important to the measurement of physical function, then assessed the feasibility of extracting these elements from a single healthcare system during the transition from acute hospital to home health care. In collaboration with Johns Hopkins Health System (JHHS) informatics and home care leaders, we determined which elements were already captured in the EHR and which were not feasible to extract within our resource constraints. We then refined the list and submitted a data request for adult patients who made the transition from acute hospital to home health care during the project period. After validation and preparation, the extracted data were securely encrypted and transferred to University of Utah Health (UUH) via secure file transfer protocol.

Results
Data from 21,702 individual hospitalized patients were included in the initial data files. Of 27 desired elements, 17 were successfully extracted. Each data element was marked as 'present' if documented at least once during hospital or home health admission, or 'missing' if absent. Administrative data had low missingness, while missingness for assessments of cognition and mobility performance in the hospital were over 70% and assessments of physical function capacity in home health were missing in over 80% of patients. However, among patients receiving home health care rehabilitation 81.7% had the expected AM-PAC mobility measure. Overall, 73% of individuals in the cohort had at least 75% of the data elements we extracted, while no one had all the data elements.

Conclusions

Advancing the collection, extraction, and use of data to track physical function for clinical decision-making, quality improvement, and research requires careful and strategic planning. Based on our experience, we recommend beginning with clear operational definitions of key constructs and identifying a specific patient cohort along with relevant data elements. Collaborating with experts in clinical documentation, EHR systems, and billing practices is essential, as is assessing data availability before extraction begins. Finally, establishing a realistic budget aligned with available resources and technology is critical to ensure feasibility and success.

Keywords: tracking physical function**;** continuum of care**;** electronic medical records

1 INTRODUCTION

Physical function is an important independent contributor to quality of life and the ability to independently move about in one's environment is an almost universal desire [1]. Mobility limitations are increasingly prevalent in older adults, affecting nearly 35% of those aged 70, and the majority of those over 85 years of age [2-4]. Older adults, and specifically those with recent hospitalization are at risk for declines in physical function that are often associated with poor health outcomes including re-hospitalization, diminished quality of life, loss of independence and death [5-8]. Among Medicare beneficiaries, older adults with mobility limitations have nearly $3000 higher total healthcare expenditures, $300 additional out-of-pocket expenses annually, and approximately 14 additional hospitalizations per 100 beneficiaries [9] than those without such limitations. To better understand and address this important problem physical function must be tracked in a standardized way and across the continuum of care.

About 17% of U.S. adults over age 65 have a hospital stay annually [10], over a third are discharged at a functional level lower than admission, and few regain preadmission function within a year [11]. Furthermore, patients often seek healthcare services when, in addition to symptom burden, some aspect of their daily physical function is interrupted [12]. This underscores the need to prioritize physical function as a meaningful patient outcome when delivering effective and accountable care. Patient important outcomes are key components of the healthcare value equation, essentially defining the overall quality of care patients receive [13].

While physical function is a critical factor in assessing healthcare value, it is not routinely nor systematically tracked across the healthcare continuum [14,15].

Understanding how physical function changes over time and across settings is crucial because it can help to detect early signs of decline, enable timely interventions to prevent further deterioration, enhance quality of life, and reduce the risk of disability, falls, and other health complications. Loss of physical function, irrespective of how it is measured is a robust predictor of hospital readmission in older adults [16]. Furthermore, physical function is a key factor that is diagnosis agnostic. This means that regardless of a patient's primary medical diagnosis (e.g., heart failure, pneumonia), their ability to move and care for themselves is a fundamental component of their recovery and overall health [17-20]. Because of this, tracking physical function can enrich not only individual patient care but the work of the entire healthcare and research team, irrespective of specific role. Electronic health records (EHR), widely adopted in the early 2000's and now used in over 95% of hospitals and medical practices [21] have created an opportunity to improve tracking of health outcomes like physical function across time and healthcare settings. However, this potential is largely unrealized because of a lack of common language and standardized assessments for physical function; different disciplines often use disparate measures, making longitudinal tracking difficult.

Despite the promise of the EHR playing a key role in transforming healthcare into a more effective, and accountable system, use of the EHR to collect and extract data that can be used to drive clinical decisions, meaningful quality improvement, and clinical research remains

elusive, particularly as it pertains to the measurement of physical function, a complex construct that encompasses multiple dimensions like mobility, balance, and endurance, and is influenced by a wide array of factors including cognition, social support, and the environment.

The purpose of this paper is to identify challenges and recommendations for using EHR data specific to the measurement of physical function and how it changes over time and across care settings, for clinical care and research. To illustrate these challenges, in this paper we provide an example of the process, barriers, and facilitators for acquiring key indicators of physical function from the EHR of a single, large healthcare system. This system was chosen because they have a robust and systematic process to collect and track physical function within the hospital and into home health care[22-28]. Specifically, we will 1) describe the process used to identify data elements impacting or directly measuring physical function, 2) the process to extract those metrics, 3) descriptively report the metrics we obtained, and 4) discuss challenges and recommendations for obtaining and using those metrics.

2 PROCESS

2.1 Identification of Data Elements Reflecting Physical Function

Our initial steps for identifying relevant data for understanding changes in physical function have been published previously [1], but for context we briefly summarize those activities here. We gathered a diverse group of individuals including patients, physical and occupational

therapists, nurses, case managers, physicians, healthcare administrators, health informaticists, and health services researchers. These stakeholders represented three different health care systems and settings including the acute hospital, home health and skilled nursing. These stakeholders participated in a 4-round modified Delphi process. Additionally, two focus groups of the remaining stakeholders offered further insights.

The first three rounds were conducted remotely and anonymously to create a list of potential data elements and rank how critical and feasibly obtainable they might be. In this first round, we identified 99 potential data elements across nine domains: physical function, participation, adverse events, behavioral/emotional health, social support, cognition, complexity of illness/disease burden, healthcare utilization, and demographics. In the fourth, in-person round, we finalized the critical and what we perceived as feasibly obtainable list of data elements resulting in 27 individual data elements. Of these, we anticipated that 20 could be routinely accessed through the EHR (Administrative Data), while the remaining seven, not necessarily routinely collected, required either patient or clinician effort (Patient/Clinician Input Data) (Table 1). Focus group participants confirmed the results from the modified Delphi process. Importantly, this process confirmed that a broad data set was necessary to understand physical function.

2.2 Data Acquisition

After identifying these data elements, we aimed to test the feasibility of extracting them from a single healthcare system across a single specific transition of care, acute hospital to home

health care, between July 2016 and March 2021. While these data were largely present in the EHR of this system, identification of their location and then acquiring them through database extraction while adhering to patient and business privacy and confidentiality concerns required substantial effort and collaboration between researchers and informaticists.

2.21 Initial Planning

We met with the Director of Rehabilitation Informatics of Johns Hopkins Health (KD) and the Rehabilitation Supervisor of Johns Hopkins Home Care (DB) to compare the list of desired data elements with those already being collected by providers in the system. We determined that 10 data elements were either not already part of routine care documentation or could not be extracted from the EMR given our available resources (i.e., money and time) (Table 1). We also discussed the documentation practices and the general location of the remaining items in the EHR (e.g., flowsheet location). After this, the Director of Rehabilitation Informatics of Johns Hopkins Health met with representatives from the Johns Hopkins Hospital (JHH) Core for Clinical Research Data Acquisition (CCDA) to finalize the list of data elements and their respective locations. This allowed the JHH CCDA to provide an estimated budget for the work which was then reviewed and approved by the research team.

2.22 Formal Data Acquisition

A data request was submitted to the JHH CCDA using a list of data field names and Epic Flowsheet IDs for either JHH acute or Johns Hopkins Medicine Home Care (JHM). We included adult patients discharged home with home health services from JHM during the project period.

The Flowsheet IDs were gleaned by the Director of Rehabilitation Informatics at JHH from the front-end builder view of Epic. The CCDA data analyst used a multi-row SQL query to extract the requested data elements. That data was validated by technical review prior to being sent to the Director of Rehabilitation Informatics at JHH for clinical validation. Clinical validation consisted of front-end chart review of the identified data fields. Due to established research relationships with the acute care team, clinical validation of data from JHH acute care was more easily achieved. In contrast, since this process was new for the Home Care team, validating Home Care data required the recruitment of a home care supervisor (DB).

The data were comprised of 27 data elements from more than 35 discrete data fields. The discrete data fields came primarily from flowsheets and 'smart data elements' and included calculated assessment scores (e.g. SLUMS score), custom list values (e.g. bathroom set up), and text fields (e.g. type of home). Each data element was associated with a unique deidentified patient identifier, a unique deidentified encounter number, and the date/time of documentation.

The data was saved in a secure, HIPAA-compliant folder on a JHM virtual desktop. Once validated, fully extracted, and prepared, the data files were encrypted and transmitted via secure file transfer protocol to University of Utah Health (UUH). The password was shared with the UUH research team to unencrypt and open the files. UUH Information Technology allowed secure file transfer across their firewall from the Johns Hopkins server IP address via the Secure Socket Shell Protocol (SSH).

3 RESULTS

3.1 Description of the Acquired Data

3.1.1 Overview of the Cohort

Data from 28,658 inpatient admissions for 21,702 individual patients were included in the initial

data files. There were 4,332 individuals with more than one admission. For these individuals,

we examined only the first admission during the study window, resulting in one inpatient

admission for each of 21,702 individuals. We then identified the corresponding home health

episode of care that followed that inpatient admission.

3.1.2 Data Elements Omitted

We were unable to obtain 10 of the 27 data elements identified by the expert panel due to

resource constraints (Table 1), although with unlimited resources, we likely would have been

able to extract data related to these items. These included injurious falls, deep vein thrombosis,

hospital acquired pressure injury, hospital acquired pneumonia, medications, case mix index,

surgery type, and pain. For example, we found that *pain* was documented in many different

ways in the medical record. Some of these included a Visual Analogue Scale (0-10), the FACES

Wong-Baker scale (0-10 with corresponding diagrams of faces), the Behavioral Pain Scale which

evaluates facial expressions, body movements, muscle tension and compliance with the

ventilator, and lengthy subjective descriptions related to body area and aggravating or relieving

factors. Reliably acquiring a measure of pain for each patient would have required additional

resources like natural language processing and significantly more budget than we had

anticipated when designing our original project. Another example of resource intensive data

are *medications*, which we also knew were present, but would have required extraction logic of

some complexity. Medications are prescribed through inpatient and outpatient orders but

delivered via the "MAR" (medication administration record) for inpatients and filled by outside

pharmacies for outpatients. Medication orders are often started, changed, stopped, and

restarted, particularly in acute care. Inpatient lists may include many medications, dosages,

routes, and frequencies during an admission. Medication reconciliation records merge home

medications with new hospital medications but are sometimes incomplete or missing. We also

found another data element, *injurious falls*, was not documented in the regular EHR but in a

separate database for risk management and reporting and not available to us.

3.1.3 Data Elements Extracted

Our goal was to assess the feasibility of obtaining the identified data elements related to

physical function from the EHR, not to describe the functional status of these individuals. As a

result, when examining the data we determined if each individual had at least one instance of

each data element documented within the appropriate setting of care. If there was one

instance of the data element, we labeled it as 'present' for that individual; if there was not a

value documented for the given data element, we labeled it as 'missing'. To examine the

feasibility of our data extraction, we report the proportion of individuals with each data

element 'present' or 'missing.' We were able to locate and had resources to extract 17 of the 27

individual data elements we wanted (10 administrative, 7 patient/clinician input in the

inpatient and/or home health settings). The number present and number and percentage of missing records for each element is listed in Table 1.

For many administrative data elements, the missingness was below 1%; however, for assessments of cognition (Cognition, CAM-ICU) and mobility performance in the hospital (JH-HLM) missingness was over 70% and assessments of physical function capacity (AM-PAC Mobility, AM-PAC Activity) in home health were missing in over 80% of patients. This does not reflect a failure of health care providers to do their job but rather a policy and practice decision that these assessments are not needed for many patients. While we did not expect all patients to have all data elements, some of these numbers, (e.g., AM-PAC Mobility, AM-PAC Activity in the home health setting) were lower than expected. We then performed a secondary analysis with the subset of patients who received home health rehabilitation services. Only those who received home health rehabilitation services were expected to have an AM-PAC basic mobility measure and, in fact 81.7% (3553/4345) did.

Of note, when examining rehabilitation utilization (i.e., physical, occupational, and speech therapy), we assumed that if an individual had an evaluation CPT code for a specific rehabilitation discipline billed, they received care from that discipline; on the other hand, if there was no evaluation code billed, we assumed that the individual did not receive therapy from that discipline. In both cases, we had information about utilization. In other words, even if no CPT was billed it was informative, and we considered this data element to be 'present.'

The involvement of rehabilitation therapists (physical and occupational therapists and speech language pathologists) is relevant to changes in physical function and so was among the data we sought to acquire. Using therapist procedural codes as indicators of rehabilitation therapist visits, we were able to quantify the involvement of each of these disciplines in each patients care. We summarize this involvement as 'utilization' in Table 2. This summary indicates what proportion of patients received at least one visit from each of these rehabilitation therapists during their admission or home health episode of care. Most patients in the acute hospital were seen by a physical therapist but less than half by an occupational therapist or speech language pathologist. In home health a large majority of patients were not seen by any rehabilitation therapist.

3.1.4 Completeness of Extracted Data

The expert panel identified all these data elements as important for understanding physical function. As a result, we were interested in the proportion of data elements found for each individual. In other words, we examined how 'complete' the measures of physical function were in our cohort. The 17 data elements that we attempted to extract were represented by 20 unique data fields because certain data elements, such as cognition, were represented across multiple data fields in the EHR. Figure 1 shows the distribution of patients based on the proportion of these 20 fields successfully obtained. Seventy three percent (15846/21702) of the individuals in the cohort had at least 75% (15/20) of the data elements we extracted, while no one had all the data elements.

3.2 DISCUSSION

3.2.1 Primary Challenges

After reaching consensus on a core set of data elements essential for measuring physical function—elements deemed both important and feasible to collect and extract from the electronic health record (EHR)—this project set out to identify the challenges and to make recommendations for obtaining these data for clinical care and research. Drawing on the EHR of a single large healthcare system, spanning the transition from acute care to home health care, we partially achieved our objective. The challenges we encountered fell into several key categories: data generation, storage, and extraction; data cleaning and validation; defining the patient cohort; difficulties linking data across care settings; and planning for adequate resources to manage the types of data involved. We learned that despite our planning and prior experience we were underprepared for some of these challenges. Below we discuss specific challenges we faced in the current project.

Even when data are entered into discrete fields, several factors make acquisition of usable data challenging. A major challenge was understanding how, when, and by whom data were generated, and where they were stored in the EHR. We observed that different patient care providers often documented the same clinical construct using different data elements and at varying time intervals, resulting in a complex dataset. Additionally, many critical data elements represent multidimensional constructs that are not collected in the same way by all providers

such as cognition, pain, changes in medical status, or medication use. These are documented by different providers at different times and in different ways.

We encountered significant challenges in cleaning and validating data due to some of the issues discussed in the previous paragraph. This highlighted to our team the importance of building in time and effort for determining clearly defined operational definitions for our key constructs. For example, "primary diagnosis" appeared in the EHR in multiple forms. We ultimately chose to use the MS-DRG classification; however, this decision may have led us to document the primary diagnosis differently than if we had used an alternative source. We also faced challenges with identifying the timing of events that we suspect came from differences between date counts and day counts. Formatting discrepancies like these also require proactively allocating time and effort to resolve them. Additionally, we encountered challenges in extracting administrative data related to clinical events such as falls, DVTs, hospital-acquired pressure ulcers, and pneumonia. We suspect that many of these issues could have been avoided by spending more time and resources establishing clearer operational definitions and assessing data availability before initiating extraction. Identifying what data is needed, its source, and its accessibility—early in the project—would save considerable time and resources.

Common data models, such as PCORNet (Patient-Centered Outcomes Research Network), may ultimately facilitate the cleaning and validation process. These models standardize health data formats across participating healthcare systems harmonizing terminology and establishing uniform data definitions, formats, and coding systems across different healthcare organizations

[29]. The current challenge is that many of the variables identified by our stakeholders as essential data elements for physical function are not well represented in many common data models [30].

Cohort definition was another critical step, especially for data validation. Because not all patients receive the same services or interact with the same provider types, we needed to determine which patients were expected to have specific data elements. For example, only some home care patients receive rehabilitation services, and only rehabilitation providers collect our target mobility and activity measures in that setting. In contrast, hospital nurses, in addition to rehabilitation therapists, collect our target mobility data making it available on nearly all patients during hospitalization. Thus, tracking physical function into home health reduced our sample size more than expected. Moreover, a subset of patients likely received out of network homecare services, reducing the sample size even further. Additionally, clear indicators of admission and discharge from both hospital and home care were not consistently defined or recorded. While our project utilized data from a single healthcare system, we underestimated the complexity involved in connecting patient data between acute hospitalization and home health care.

The barriers we experienced to obtaining all the data we were initially interested in stemmed primarily from budget limitations. In particular, we underestimated the effort required for informatics resources. These challenges highlight the importance of collaboration with individuals who have deep knowledge of clinical documentation, EHR access, and billing

practices—namely, clinicians, managers and informaticists. In this instance, earlier collaboration with EHR clinical-technical subject matter experts from both acute care and home care would have helped us more realistically determine the feasibility and expense of extracting data across care settings. The importance of engaging these team members early in the research planning cannot be overstated. Sharing a common language with data architects and other technical experts trained in the specifics of the EHR vendor products, the clinical-technical subject matter experts can mitigate many of the challenges we encountered [31].

3.2.2 Recommendations

Advancing the collection, extraction and use of data to track physical function to drive clinical decisions, meaningful quality improvement, and clinical research requires significant and thoughtful advanced planning. Recommendations from our experience include:

1. Begin by creating clear operational definitions for key constructs.

2. Identify specific cohort and data elements expected to be associated with that cohort.

3. Establish a collaboration with individuals who have deep knowledge of clinical documentation, EHR access, and billing practices.

4. Assess data availability prior to initiating extraction.

5. Establish a realistic budget to leverage available resources and technology.

4 CONCLUSIONS

Physical function is a critical and measurable outcome for both clinicians and researchers seeking to improve the value of health care. As a diagnosis-agnostic indicator, physical function offers valuable insights regardless of whether patients receive services from a rehabilitation provider. Declines in physical function can signal increased risk for poor health outcomes, and early recognition creates opportunities to intervene and potentially alter the trajectory of a patient's health. Standardizing how physical function is measured has become increasingly important—particularly as researchers aim to curate and integrate data across health systems using common data models. In this paper, we highlighted specific challenges and proposed potential solutions for using EHR data to track physical function across care transitions, specifically from acute care to home health care, within a large health system. While clinical data in EHRs are complex and often imperfect, we offer several practical recommendations for future efforts in this space.

Data Element	Setting	Present	Missing (n, %)
Administrative Data			
Age	Acute	21702	0, 0.0
BMI	Acute	21638	64, 0.3
Race	Acute	21643	59, 0.3
Sex	Acute	21702	0, 0.0
Zip Code	Acute	21678	24, 0.2
Insurance	Acute	21284	418, 1.9
Injurious Fall	Acute	Not obtained due to resource limitation	
Deep Vein Thrombosis	Acute	Not obtained due to resource limitation	
Hospital Acquired Pressure Injury (III or IV)	Acute	Not obtained due to resource limitation	
Hospital Acquired Pressure Injury (Any)	Acute	Not obtained due to resource limitation	
Hospital Acquired Pneumonia	Acute	Not obtained due to resource limitation	
All Cause 30 Day Readmission	Acute	21197	505, 2.3
Hospital Discharge Disposition	Acute	21702	0, 0.0
MS-DRG	Acute	21702	0, 0.0
Case Mix Index	Acute	Not obtained due to resource limitation	
Surgery	Acute	Not obtained due to resource limitation	
ICU Stay	Acute	Not obtained due to resource limitation	
Hospital LOS	Acute	21702	0, 0.0
Medication count	Acute	Not obtained due to resource limitation	
Physical therapy, occupational therapy, speech, language pathology utilization	Acute	21702	0, 0
	HH	21702	0, 0
Patient/Clinician Input Data			
Cognition	Acute	7400	14302, 65.9
	HH	0	21702, 100.0
CAM-ICU	Acute	6776	14926, 68.8
AM-PAC Mobility	Acute	21042	660, 3.0
	HH	3739	17963, 82.8
AM-PAC Activity	Acute	20857	845, 3.9
	HH	780	20922, 96.4
JH-HLM	Acute	6322	15380, 70.9
PLOF	Acute	5767	15935, 73.4
Pain interfering with movement	Acute	Not obtained due to resource limitation	
	HH	Not obtained due to resource limitation	

Possible unique patient n = 21702, present=data present based on CPT code billed to discipline specific cost center (Acute) or visit type (Home Health - HH), missing=data missing in report

Table 2. Utilization

Setting	Discipline	Received	Not Received (n, %)
Inpatient			
	OT	9288	12414, 57.2
	SLP	3150	18552, 85.5
	PT	13552	8150, 37.6
Home Health			
	OT	2250	19452, 89.6
	SLP	560	21142, 97.4
	PT	4163	17539, 80.8

Possible unique patient n = 21702

Figure 1. Proportion of data elements collected per patient
