Keywords: Lifestyle physical activity, all-cause mortality, machine learning

Abstract

Background: Vigorous intermittent lifestyle physical activity (VILPA) completed through normal daily living may offer a time-efficient avenue to accrue physical activity in a behaviorally sustainable manner. However, no research to date has explored its association with mortality in a nationally representative population.

Objectives: To examine the dose-response association between VILPA and mortality risk in a nationally representative sample of US adults.

Methods: This study included a nationally representative sample of 3,293 US adults from the 2011-14 National Health and Nutrition Examination Survey (NHANES) who self-reported no participation in structured exercise (52.3% female; mean age: 50.7 [SD: 16.6 years]. The dose-response relationship between VILPA and all-cause mortality was estimated using multivariable-adjusted cubic splines. Average daily frequency (bouts/day) and duration (minutes/day) of VILPA bouts lasting up to one minute were measured using a wrist-worn accelerometer.

Results: Over the mean (SD) 6.7 (1.4) year follow-up period, 290 all-cause mortality events occurred. Compared to the referent point (0 bouts per day), there was an L-shaped dose-response association where the median frequency (5.3 bouts per day) was associated with a 44% lower risk of all-cause mortality (HR: 0.56; 95% CI: 0.39, 0.82). The dose response curve was less steep beyond approximately 8 bouts per day (HR: 0.46; 95% CI: 0.28, 0.77). Daily duration of VILPA demonstrated a near-linear association with all-cause mortality risk with a median duration of 1.1 minutes associated with an HR of 0.61 (95% CI: 0.42, 0.88).

Conclusions: Short bursts of intermittent vigorous physical activity were associated with meaningful health benefits in a nationally representative sample of US adults. Future trials are warranted to investigate the effectiveness and feasibility of VILPA-based interventions.

INTRODUCTION

Physical inactivity is a major risk factor for all-cause, cardiovascular, and cancer mortality[1], presenting an unresolved public health challenge. Despite decades of public health efforts, only approximately 20-25% of adults engage regularly in leisure time physical activity[2,3]. Both previous[4,5] and current iterations[6,7] of physical activity guidelines are largely derived from self-report questionnaires, primarily capturing activities lasting >10 minutes. Recent guidelines such as the 2018 Physical Activity Guidelines for Americans[6] and the World Health Organization 2020 Guidelines on Physical Activity and Sedentary Behavior[7], promote "all activity counts" messaging, implicitly recommending short bouts of physical activity. These recommendations were primarily informed by cross-sectional studies that generically assessed non-contextual and non-intensity-specific bouts lasting <10 minutes[8], with no direct evidence of the role of physical activity coming from very short bouts.

Recent wearable based evidence from a sample of non-exercising adults in the UK Biobank has highlighted the potential health value of such brief bursts, specifically in the form vigorous intermittent lifestyle physical activity (VILPA: bouts lasting up to 1 minute each) and moderate-to-vigorous intermittent lifestyle physical activity (MV-ILPA: bouts <3 minutes)[9-12]. For example, 4.4 minutes per day of VILPA was associated with a 26-30% lower risk of all-cause and cancer mortality and a 32-34% lower risk of cardiovascular mortality[9]. Such studies incorporating wearable devices and novel

machine learning methods[9-13] permit the study of high-resolution "micro-patterns" of physical activity[9,10], such as VILPA and MV-ILPA outlined above. This more granular examination of physical activity patterns was not previously possible in studies relying on self-report-based measures or even previous generation accelerometry studies[14] with lower data resolution (1 min epoch).

From a behavioral standpoint, intermittent short bursts of incidental physical activity offer a theoretical advantage as they can be easily integrated into day-to-day life by individuals who face common barriers to traditional exercise such as a lack of time, motivation, or access to facilities[15]. These collective barriers contribute to an environment that is often not conducive to participation in traditional structured exercise or long bouts of incidental movement. Previous studies[9,11-13] exploring the relationship between VILPA and mortality used the UK Biobank, a cohort that is more educated, has fewer chronic health conditions, less obesity, and is more socioeconomically advantaged compared to the general population[16]. To date, no study has examined the health effects of brief intermittent bursts of vigorous physical activity incorporated into daily living activities with health outcomes among a nationally representative dataset of US adults.

The aim of this study is to examine the dose-response association between daily VILPA frequency and duration with all-cause mortality risk in a nationally representative sample of US adults.

METHODS

Study Design and Participants

This prospective cohort included non-exercising adults aged ≥20 from the National
Health and Nutrition Examination Survey (NHANES) during 2011-2014. NHANES is an
ongoing annually collected survey that employs a multi-stage probability sampling
design to capture the health and lifestyle habits representative of the
noninstitutionalized US population[17]. This sampling design includes oversampling
certain subgroups, such as racial/ethnic minorities, low-income individuals, and older
adults, to improve the precision of prevalence estimates in these subgroups when
incorporating survey weights that account for oversampling, non-response and
poststratification[17]. All NHANES protocols have been approved by the National Center
for Health Statistics and informed consent was collected from each participant.

From 2011-2014, during the mobile examination visits, a sub-sample of 14,693
participants from the main NHANES survey were invited to wear wrist-worn trackers
(ActiGraph model GT3X+, Pensacola, FL) on their non-dominant hand for 7-days[17-19].
Participants were instructed to wear the devices for 24 hours per day while sleeping and
awake, including while in the bath, shower, or when swimming. The devices were
programmed with a sampling rate of 80 Hz and distributed to participants at the end of
the mobile examination visits[17-19]. To be included in our analyses, participants must
have worn the device at least three valid monitoring days (>16 hours), including at least

one weekend day[9-12,20,21]. We excluded all subjects who incorrectly wore the device on the dominant wrist, reported mobility issues such as difficulty walking, or required equipment to walk (**Supplement Fig. 1**)[22].

As in previous studies[9-13,23,24], to enable the examination of the health effects of incidental physical activity, we included only participants who reported no moderate or vigorous leisure time exercise participation in a typical week, as captured by the Global Physical Activity Questionnaire at baseline[17-19]. The examples provided include participating in recreational sport activities such as running, basketball, golf, bicycling, golf, or walking (**Supplement Table 1**).

Ascertainment of Mortality

Mortality data was ascertained via the National Center for Health Statistics where participant information was linked to the National Death Index. The underlying cause of death was reported using the International Statistical Classification of Diseases and Related Health Problems (ICD-10) code. Cardiovascular mortality was classified as total deaths from diseases of the heart (I00-I09, I11, I13, I20-I51) or cerebrovascular events (I60-I69). Cancer mortality was classified as deaths caused by malignant neoplasms (C00-C97). All-cause mortality included deaths from all known causes (**Supplement Table 2**). The follow-up period was defined as the duration from the mobile examination (i.e., date of accelerometry collection) to the date of death or December 31st, 2019 for

those without a mortality event. Analyses were performed between January 1st and August 1st 2024.

Device-Measured Physical Activity Classification

As described in detail previously[9-13,25], we used a validated two-stage random forest intensity classification schema to determine specific activities and intensity (84.6% accuracy across all intensities; see **Supplement Methods**). In brief[9-13,25], this classifier first categorizes each 10-second window as one of four activity classes including: sedentary (lying or sitting still), standing utilitarian (for example, ironing a shirt, washing dishes)), walking (for example, gardening, active commuting, mopping floors), or running/high energetic activities (for example, active playing with children). At the second stage, these activity classes are then assigned one of four intensities including: sedentary, light (<3 METs), moderate ($\geq$3 to <6 METs), and vigorous activities ($\geq$6 METs). Walking activities were classified using the raw magnitude of wrist movement acceleration using milligravity (mg), defined as light (<100 mg), moderate (≥100 mg) and vigorous (≥400 mg) intensity. The vigorous intensity definition and bout length selection of up to 1 minute in duration was based on both laboratory data and the naturally occurring bout length in the present and previous studies[9,11-13]. In our previously collected laboratory data[26], we determined the time to elicit a VILPA as 73.5 s (SD 26.2 s) based on three criteria, including oxygen uptake (%V02), maximal heart rate

(%HRmax), and rating of perceived exertion (Borg scale). Additional details regarding the VILPA definition and bout length selection are provided in the **Supplemental Methods**.

Statistical Analysis

The frequency and daily duration for VILPA were truncated at the 2.5 and 97.5 percentile to reduce the potential influence of sparse data[9,20]. We estimated multivariable adjusted absolute risk for all models using log-link Poisson Regression with robust standard error to calculate the dose-response association of VILPA frequency and daily duration with mortality risk[13,20]. We assessed the dose-response association between VILPA with mortality risk using restricted cubic splines with 0 bouts per day and 0 minutes per day for daily duration as the reference (knots placed at the 10th, 50th, and 90th percentile)[9,10]. Time-to-event associations of VILPA with mortality risk were estimated using Cox proportional hazards models. Fine-Gray sub-distribution hazard models were applied to address competing risks for cardiovascular mortality and cancer mortality. To provide point estimates for the dose-response associations, we report the hazard ratio (HR) for the median of each exposure and the minimal volume dose (50% of the optimal dose)[9,20,27]. We identified the inflection point[28] in the dose-response curve by examining the difference between successive HRs (**Supplement Fig. 2-3**). To account for the complex survey design, we applied the weights to all

models which ensures the estimates are representative of the noninstitutionalized US population[17]. All models met the Cox proportional hazards assumptions.

As in previous analogous analyses [9,10,13,20], we adjusted for self-reported age, gender, education, race/ethnicity, socioeconomic status (income-to-poverty ratio), fruit and vegetable intake (servings per day), accelerometry estimated sleep duration, medication (glycemic control, lipid-lowering, or blood pressure), discretionary screen time, previous cancer, previous cardiovascular disease, and familial history of cardiovascular disease or type-two diabetes[9,10,13,20]. A detailed description of each covariate is provided in **Supplement Table 3**. The models with VILPA frequency (bouts per day) as the exposure were additionally adjusted for total physical activity energy expenditure (PAEE)[29,30]. The models with VILPA duration (minutes per day) as the exposure were additionally adjusted for light and moderate PAEE and the daily VILPA duration from bout lengths >1 minute[9-11,13]. All missing covariates were estimated using a random forest multiple imputation by chained equations model (5 imputed datasets).

Sensitivity Analyses

To test for the possibility of sex-based differences, we tested for multiplicative interaction and the relative excess risk due to interaction. We completed several sensitivity analyses to examine the robustness of our findings to reverse causation and other possible biases. First, we excluded underweight participants (BMI of <18.5),

participants reporting a self-perceived rating of poor health, participants with prevalent CVD or cancer, or participants with a mortality event in the first 5 years of follow-up. Second, we created additional models using the median value of the exposure as the reference point in the dose-response association[10,20] or excluding individuals with extreme VILPA values. Third, we repeated the main analyses with adjustment for cardiometabolic risk factors, which are possible mediators in the association between physical activity and mortality risk[10,31]. We provide a sensitivity analysis adjusting for a more comprehensive diet quality indicator (Healthy Eating Index 2015)[32] to address potential confounding by other dietary factors[22]. In another analysis, we excluded individuals with missing covariate information rather than applying multiple imputations to address potential imputation bias[33]. To test for possible misclassification of non-exercisers, we completed a sensitivity analysis repeating the main analyses with two alternative non-exerciser definitions a) excluding adults who self-reported only completing recreational VPA and b) excluding adults who self-reported ≥1 day per week of recreational MVPA). We also conducted a sensitivity analysis by treating accidents and residual deaths (i.e., contains a mixture of accidental and other causes of deaths that do not have clear links to physical inactivity) as a competing interest using Fine-Gray sub-distribution hazard models (see **Supplement Table 2** for ICD-10 Codes).

Additional Analyses

For reference, we also examined associations of our exposures with cardiovascular mortality and cancer mortality, two outcomes with a relatively small number of events. To enable a direct comparison of VILPA associations with our previous work in middle-aged adults[9-13], we repeated the core analysis in adults ≥40 years old. Additionally, to assess the possibility of unmeasured confounding, we calculated e-values for each model[34]. There was no problematic multicollinearity present in any of the models (**Supplement Table 4**).

All analyses and graphics in this study were conducted using the survival, survey, RMS, mice, and ggplot2 packages in R statistical software (v.4.3.1). This study followed the Strengthening the Reporting of Observational Studies in Epidemiology Guidelines (STROBE).

RESULTS

Participant characteristics

The final analytical sample included 3,293 non-exercising adults (52.3% female) with a median age of 50.7 [SD: 16.6] years (**Table 1**). The sample included a substantial proportion of adults (44%) consuming medication for glycemic control, lipid lowering, or blood pressure management, with 9.8% reporting a history of cardiovascular disease and 9.3% reporting a history of cancer. Cardiometabolic health markers included a mean BMI of 29.4 (SD = 6.6), waist circumference of 98.2 cm (SD = 14.2), fasting blood

glucose of 105.5 mg/dL (SD = 24.1), triglycerides of 119 mg/dL (SD = 70.9), total

cholesterol of 191.8 mg/dL (SD = 38.4), LDL cholesterol of 113.6 mg/dL (SD = 33.0),

systolic blood pressure of 122.6 mmHg (SD = 16.5), and diastolic blood pressure of

70.7 mmHg (SD = 10.8). The majority of participants had complete covariate information

(92.9%). The vast majority of all vigorous bouts lasted <1 minute in duration (95% of all

bouts) with a median bout length of 10 seconds [IQR: 20 seconds]. The median VILPA

frequency and duration were 5.3 [IQR: 8.9] bouts per day and 1.1 minutes [IQR: 2.09]

per day, respectively. Participants had a median wear time of 23.1 [IQR: 1.2] hours per

day. Over a 6.7-year median follow-up period, corresponding to 22,183 person-years,

there were 290 all-cause mortality events, 49 cardiovascular mortality events, and 48

cancer mortality events.

VILPA and all-cause mortality risk

In the fully adjusted analytical model, both VILPA frequency and duration displayed an

L-shaped association with lower all-cause mortality risk. The minimum daily VILPA

frequency (0 bouts per day, 9.6% of the sample) and median (5.3 bouts per day)

frequency of VILPA were associated with an absolute risk of 95.7 (95% CI: 55.3, 165.4)

and 55.0 (95% CI: 33.5, 90.2) per 10,000 person-years; respectively (**Supplement Fig.

4A**). The minimum daily VILPA duration (0 minutes per day; 25.1% of the sample) was

associated with an absolute risk of 89.8 (95% CI: 52.5, 153.4) per 10,000 person-years.

The median daily VILPA duration (1.1 minutes per day) had an absolute risk of 55.7 (95% CI: 34.0, 91.3; **Supplement Fig. 4B**) per 10,000 person-years.

Compared to the VILPA frequency referent data point (0 bouts per day), we observed an L-shaped dose-response association between VILPA frequency and all-cause mortality risk (**Fig. 1A**). The median daily VILPA frequency (5.3 bouts per day) was associated with an HR of 0.56 (95% CI: 0.39, 0.82) for all-cause mortality. The slope of the dose-response curve for VILPA bouts per day began to plateau beyond approximately 8 bouts per day, corresponding to a 54% lower risk of all-cause mortality (HR: 0.46; 95% CI: 0.28, 0.77; **Supplement Fig. 2**). Compared to the referent minimum daily VILPA duration (0 minutes per day), there was a near-linear association with all-cause mortality risk (**Fig. 1B**). The median daily duration of VILPA (1.1 minutes/day) was associated with an HR of 0.61 (95% CI: 0.42, 0.88). The slope of the dose-response relationship began to plateau beyond approximately 2 minutes per day, corresponding to an HR of 0.55 (95%CI: 0.27, 0.76; **Supplement Fig. 3**). The minimal dose for VILPA bouts (4.3 bouts per day) and daily duration (1.3 minutes per day) corresponded to an HR of 0.62 (95%CI: 0.44, 0.86) and 0.57 (95%CI: 0.37, 0.85), respectively.

In adults ≥40 years old, the association between VILPA frequency and duration was attenuated, displaying a clearer L-shape relationship with all-cause mortality (**Fig. 2**).

Compared to the minimum VILPA frequency (0 bouts per day) and duration (0 minutes per day), the median VILPA frequency (3.8 bouts per day) and duration (0.8 minutes per day) were associated with an HR of 0.61 (95%CI: 0.43, 0.86) and 0.65 (95%CI: 0.47, 0.90), respectively. The minimal dose for VILPA frequency (3.2 bouts per day) and daily duration (1.1 minutes per day) was associated with an HR of 0.65 (95%CI: 0.48, 0.88) and 0.58 (95%CI: 0.39, 0.87), respectively.

Sensitivity analyses

The associations between VILPA and all-cause mortality did not significantly differ when excluding individuals with poor self-rated health (**Supplement Fig. 5**). The associations were attenuated when excluding adults with prevalent disease (**Supplement Fig. 6**) or who had an event in the first five years of follow-up (**Supplement Fig. 7**). The associations were similar when adjusting for cardiometabolic health (**Supplement Figs. 8-9**), diet quality (**Supplement Fig. 10**), or when excluding individuals with upper and lower ranges of VILPA (**Supplement Figs. 11-13**). The associations were unchanged when treating accidents as a competing interest, while treating residual deaths as a competing interest largely attenuated the associations (**Supplement Figs. 14-15**). There were no materially different results when using the median as the referent point (**Supplement Fig. 16**), different definitions of non-exercisers (**Supplement Figs. 17-18**), or when excluding individuals with missing covariate information (**Supplement Fig. 19**).

Additional Analyses

The dose response relationship for VILPA duration with cardiovascular mortality was similar to all-cause mortality in direction but with considerably larger uncertainty due to the very low number of events (**Supplement Fig. 20**). There was no clear association between VILPA frequency with cardiovascular mortality nor between VILPA frequency or duration with cancer mortality, possibly also due to the very low number of events (**Supplement Fig. 20-21**). There was no significant interactive or synergistic association between sex and VILPA with all-cause mortality (**Supplement Table 5**). E-values indicated that to attenuate the primary findings to null, the association of an unmeasured confounder for VILPA frequency and duration would need to be 3.59 (lower 95% CI: 1.96) and 3.59 (lower 95% CI: 2.00), respectively (**Supplement Table 6**).

DISCUSSION

Statement of Principle Findings

This is the first US-based study on the health effects of brief intermittent vigorous activity embedded into daily living. We found that daily VILPA frequency was inversely associated with all-cause mortality such that accumulating 5-6 very brief bouts lasting <1 minute each, was associated with a 42-47% lower risk of all-cause mortality. We also found a near-linear inverse association between VILPA duration and all-cause mortality

risk, indicating that relatively modest amounts of VILPA, such as the median duration of just over one minute, were associated with a 39% lower risk of all-cause mortality. Our findings were robust to a wide array of sensitivity analyses seeking to explore potential biases, including reverse causation. There was no clear association of VILPA with cardiovascular or cancer mortality, however, this is potentially due to the low number of events, which are likely underpowered for meaningful interpretation.

Previous physical activity research using the US representative NHANES data has primarily focused on context-agnostic total physical activity in the form of total daily steps[35,36] or MVPA[14,37-41] and did not examine the potential health benefits of bouts lasting <10 minutes in duration[14,42]. To date, only two studies have examined the association between short bouts of MVPA (i.e., 5 or 10 minutes in duration) with all-cause mortality using prospective data[14,42]. This relatively underexplored aspect of physical activity is important, as the vast majority of adults complete their daily moderate or vigorous physical activity in brief bouts lasting <3 minutes in duration (e.g. 88% of all MVPA bouts in the UK Biobank[10,43], and 92% of bouts in MVPA NHANES). This US study is the first, to our knowledge, in a population representative sample, examining the dose-response associations of brief bouts of VILPA[9] lasting <1 minute in duration with all-cause mortality.

In comparison to the previous analogous work examining VILPA frequency and duration in the UK Biobank[9,10,13], our findings indicate a larger magnitude of risk reduction per exposure unit. For example, the median VILPA of 4.4 minutes per day in the UK Biobank was associated with a 38% lower risk of all-cause mortality[9], an effect size that was elicited in NHANES from 1.1 minutes per day. Moreover, VILPA frequency demonstrated steep beneficial L-shaped association with all-cause mortality where the steepness of the dose-response curve began to diminish beyond 8 bouts per day, associated with a 54% lower risk of all-cause mortality. Of note, the VILPA bouts in NHANES occurred less frequently (Median: 5.3 [IRQ: 8.9] bouts per day) and were shorter (Median: 10 seconds [IQR: 20 seconds] each) when compared to the UK Biobank (Median [IRQ] 10.1 [12.8] bouts per day and lasting 25 [6] seconds each).

The noticeable difference between the observed effect size for VILPA in the NHANES dataset and the UK Biobank may be partially attributed to variations in sociodemographic and lifestyle characteristics between the cohorts and the different prevalence of vigorous physical activity[16,44]. For example, compared to the non-exercisers in UK Biobank participants, the current NHANES sample had a higher average BMI (29.4 vs. 27.6), contained over twice the proportion of current smokers (24.4% vs. 9.2%), and completed approximately half the total daily MVPA (18.4 min vs. 30.3 min/day)[9,10,13]. These differences in cohort profiles likely reflect a combination of the non-representative nature of the UK Biobank, which compared to the general UK

population, is more socioeconomically advantaged, less obese, less likely to smoke or drink, and reported fewer self-reported health conditions[9,10,13,16] and the high prevalence of insufficient physical activity in the US[44]. These collective differences may contribute to a lower fitness and functional capacity in the NHANES sample, potentially resulting in a greater relative benefit from vigorous physical activity. Additional evidence from the UK Biobank further supports this in the context of incidental physical activity, wherein inactive adults achieved up to two-fold lower mortality risk from intermittent physical activity when compared to adults meeting the physical activity guidelines[43]. However, it is important to note that the non-exerciser status was determined using different self-report questionnaires in the UK Biobank and NHANES datasets, which may have influenced the comparisons made.

This study expands on previous findings[14,39,40] among US adults, by demonstrating meaningfully lower risk associated with modest amounts of vigorous-intensity physical activity accrued through very short bouts. While the magnitude of risk reduction observed in our study is substantial, it may be biologically feasible, particularly given this study examines a population of highly inactive and overweight individuals. Previous research has shown greater health benefits from brief bursts of high-intensity training (HIIT) in obese or inactive adults when compared to healthy weight active adults[45]. These benefits include various cardiometabolic risk factors that additively contribute to mortality risk, including improved cardiorespiratory fitness, enhanced endothelial

function, body composition, reduced blood pressure, and improved glycemic control[45,46]. While no current recommendations exist for the frequency of vigorous bouts per day, our findings align well with previous evidence suggesting that as little as 3-6 bouts per day of high-intensity movement lasting for 6-20 seconds (e.g., stair climbing) can improve cardiometabolic profiles in both young and older adults[47-49].

The present results highlight some promise for brief, intermittent activity, especially considering that the majority of US adults may not be keen, able, or willing to engage in regular structured exercise[50]. Previous qualitative work[15], indicates that interventions integrating such brief activity bursts into everyday tasks (e.g., active commuting, household chores, or office work) without the need for dedicated time or equipment may have feasibility advantages over traditional exercise. Commonly reported VILPA activities in a free-living environment include very fast walking, incline walking, short running bursts, outdoor gardening, carrying heavy loads during household chores, or energetic playing with children[10]. Identifying additional VILPA activities that are both widely accessible and practical could inform public health initiatives or interventions aimed at promoting brief intermittent bursts of activity as a viable alternative to those unable or unwilling to complete traditional structured exercise. This form of physical activity may offer a more feasible and appealing option for increasing movement among broad segments of the US population.

Strengths and Limitations

A key strength of this study is the incorporation of survey design weights into our analyses enabling population-representative estimates for non-institutionalized adults in the US. We also employ a novel machine-learning approach that classifies physical activity intensity in 10-second windows[25,51]. This is distinct from previous NHANES context-agnostic work which has predominantly examined accelerometry-based total amounts of PA accrued through 1-2 min epochs which are unable to capture very short bouts of VILPA[14,35-42], or self-reported leisure time physical activity[52-55]. We conducted an extensive range of additional analyses to test the robustness of our results to the risk of reverse causation, confounding, and other biases, including the exclusion of prevalent diseases and early follow-up, frail or poor health individuals, and adjustments for cardiometabolic health markers[9,10,20,22,56].

Despite these measures, the possibility for reverse causation or unmeasured confounding remains. Factors such as misreporting, temporal variation of lifestyle factors (e.g., alcohol intake, smoking, obesity), or the high prevalence of chronic diseases at baseline could have influenced the study findings. Additionally, although we accounted for a range of covariates, these were primarily collected via self-report surveys and subject to certain biases. In particular, given that both self-reported leisure time physical activity and wrist-worn accelerometry were only measured at baseline, potential shifts in physical activity patterns cannot be ruled out. Limitations of this study also include the possibility of activity intensity misclassification due to inherent

limitations of wrist-worn wearables, for example, the intensity of activities such as walking uphill or carrying objects (e.g., backpacks) may not be captured accurately[25] and may lead to an underestimation of true daily VILPA amounts. Lastly, although NHANES is designed to be a nationally representative study, selection bias may be introduced from individuals who are more willing to participate or wear the device correctly over the data collection period.

CONCLUSION

VILPA frequency and duration were associated with lower all-cause mortality risk in an L-shaped and linear manner, respectively. If effective strategies and activities for increasing VILPA can be identified, these results may have implications for future public health recommendations, as VILPA may offer a more time efficient and behaviorally sustainable option for adults unable or unwilling to regularly participate in traditional exercise.

Figure 1: Survey adjusted dose response curves of daily VILPA frequency (A) and duration (B) with all-cause mortality (n = 3,293; events = 290).

Legend: Analyses were adjusted for sex, age, income, education, ethnicity, fruit and vegetable consumption, smoking hist ory, physical activity energy expenditure from LPA and MPA, alcohol consumption, sleep duration, duration of light and mo derate intensity, discretionary screentime, medication use (glycemic control, blood pressure, cholesterol), family history of diabetes and CVD, and previous history of CVD, diabetes, and cancer. VILPA bout (A) was further adjusted by energy exp

enditure by vigorous intensity and VILPA duration (B) was further adjusted for VILPA bouts over 1-minute bout. All analyses excluded participants who had an event in the first year of follow-up. All analyses were adjusted for strata, cluster, and survey weights. Reference was set to zero for VILPA frequency and duration. Diamond, minimal dose, as indicated by the ED50 statistic which estimates the daily duration of VILPA associated with 50% of optimal risk reduction. Circle, HR associated with the median VILPA value.

Figure 2: Survey adjusted dose response curves of daily VILPA frequency (A) and duration (B) with all-cause mortality (n = 2,276; events = 272) in adults aged ≥40

Legend: Analyses were adjusted for sex, age, income, education, ethnicity, fruit and vegetable consumption, smoking history, physical activity energy expenditure from LPA and MPA, VILPA bouts over 1-minute, alcohol consumption, sleep duration, duration of light and moderate intensity, discretionary screentime, medication use (glycemic control, blood pressure, cholesterol), family history of diabetes and CVD, and previous history of CVD, diabetes, and cancer. VILPA bout (A) was

further adjusted by energy expenditure by vigorous intensity and VILPA duration (B) was further adjusted for VILPA bouts over 1-minute bout. Reference was set to zero for VILPA frequency and duration. Diamond, minimal dose, as indicated by the ED50 statistic which estimates the daily duration of VILPA associated with 50% of optimal risk reduction. Circle, HR associated with the median VILPA value. All analyses excluded participants who had an event in the first year of follow-up. All analyses were adjusted for strata, cluster, and survey weights.

Table 1: Participant baseline characteristics by VILPA duration (mins/day).

VILPA duration quartiles (mins/day)	0	<0.4	0.4-1.1	1.1-2.5	>2.5	Overall
Sample size (n)	129	791	791	791	791	3,293
All-cause mortality, n (%)	59 (45.7)	129 (16.3)	60 (7.6)	26 (3.3)	16 (2.0)	290 (8.8)
Follow up (in years), mean (SD)	5.8 (1.8)	6.5 (1.6)	6.8 (1.4)	6.8 (1.3)	6.9 (1.2)	6.7 (1.4)
Age (mean (SD))	72.6 (9.2)	62.4 (14.3)	49.9 (14.9)	45.2 (14.4)	41.8 (13.2)	50.7 (16.6)
Sex, Female (%)	68 (52.7)	468 (59.2)	455 (57.5)	404 (51.1)	327 (41.3)	1,722 (52.3)
Smoking (%)						
Current	24 (18.6)	167 (21.1)	235 (29.7)	187 (23.7)	190 (24.1)	803 (24.4)
Never	61 (47.3)	397 (50.3)	399 (50.4)	451 (57.2)	451 (57.1)	1,759 (53.5)
Previous	44 (34.1)	226 (28.6)	157 (19.8)	151 (19.1)	149 (18.9)	727 (22.1)

VILPA: Vigorous intermittent lifestyle physical activity; MPA: Moderate intensity physical activity; LPA: light intensity physical activity.

The columns breakdown corresponds to the total volume of VILPA. Values represent mean (standard deviation) unless specified otherwise. [1]Alcohol consumption measured 12 drinks/year (1 drink = 12 oz. beer/ 5 oz. glass of wine/ one and a half oz. of liquor). [2]Fruits and vegetable consumption measured in servings per day.
