**NS:** not significant

**OD:** overdose

**SE:** standard error

**Abstract**

Recent years have shown increases in overdose (OD) mortality caused by *polydrug* exposure to synthetic opioids such as fentanyl and stimulants such as methamphetamine or cocaine. The goal of this study is to understand the recent trajectory in this polydrug OD mortality, especially associated with decedents' sex and age. We carried out a cross-sectional analysis of national data for persons aged 15-74, from CDC WONDER for 2018-2024 (data for 2024 are considered provisional at the time of analysis). The outcome measure was OD mortality/100,000 population; annual data for 2018-2024 were analyzed with joinpoint regression, and the most recent years (2023-2024) were analyzed with ANOVA and multiple linear regression. Males had greater polydrug OD mortality compared to females, across 2018-2024. Sex-specific joinpoint regressions detected increases in polydrug OD after 2018, then decreases from 2023 in males, and from 2022 in females. For these polydrug OD, the mean annual percent change (APC) in 2024 versus 2023 was -36% and -31% in males and females, respectively. For synthetic opioids *without* stimulants, OD trends in 2024 versus 2023 were similar to those for polydrug OD (-42% and -39% APC in males and females, respectively). However, OD for stimulants *without* synthetic opioids showed relatively smaller changes (-3% and -2% APC in males and females, respectively). Stratification into 10-year age groups for polydrug OD revealed that mortality peaked at age 35-44 and then declined at older ages. Recent decreases in polydrug OD mortality were observed across age groups, with joinpoints detected in 2022 or 2023. These findings indicate that after increases from 2018 onward, polydrug OD mortality caused by synthetic opioids and stimulants exhibited substantial decreases in both males and females in the most recent data for 2024, across a broad age range. Because relatively small changes were observed in OD mortality caused by stimulants *without* synthetic opioids in this time period, the decreases in polydrug OD mortality are more likely to be caused by changes in exposure, prevention or intervention strategies focused on opioids rather than on stimulants. While this polydrug OD mortality has decreased in 2024, it remains at concerning levels.

**Introduction**

The United States has undergone an epidemic of overdose (OD) mortality in recent years, exacerbated during the COVID pandemic[1–3]. These high OD rates are caused primarily by synthetic opioids such as the mu-opioid receptor (MOR) agonist fentanyl or its analogs [4,5], and by stimulants such as methamphetamine or cocaine[6–9]. Importantly, the current "fourth wave" of OD has shown increases in *polydrug* exposure to these two types of compounds[7,10,11]. For example, there was a 37% increase in the annual rate of nonfatal polydrug OD caused by opioids and amphetamines, for 2019 versus 2018[12]. In addition to the risk of *knowingly* using both opioids and stimulants [13,14], there has also been a concerning increase in OD due to the concealed addition of synthetic opioids such as fentanyl in the drug supply, including counterfeit oral formulations[15,16], as well as into other illicit formulations, which are then injected, inhaled or smoked[17]. This concealed presence of synthetic opioids can further increase the risk of OD morbidity and mortality[18–20].

Overdose morbidity and mortality caused by MOR agonists is principally due to respiratory depression[21,22], whereas those caused by stimulants (mediated principally through inhibition of monoamine neurotransmitter reuptake)[23,24] are due to different mechanisms, such as cardiovascular, neurovascular or neurological insults[25,26]. Opioid OD are acutely managed by administration of MOR antagonists, principally naloxone. Notably, naloxone has become more widely available in 2023-2024, due to the approval of several over-the-counter intranasal formulations, expanding accessibility in the community, compared to prior years[27,28]. Furthermore, receipt of medications for opioid use disorder (MOUD, such as buprenorphine or methadone) also provides increased safety and decreased OD events, although MOUD receipt and adherence can vary based on social determinants of health[29–31]. In recent years there has also been increased emphasis on "low threshold" referrals for MOUD[30,32], as well as initiation of this treatment in emergency settings[33]. By contrast, there are no medical countermeasures or antidotes specifically approved for OD caused by methamphetamine or cocaine [34]. Some preclinical studies have delineated acute pharmacological interactions between synthetic opioids and stimulants (e.g., on respiratory depression)[35]. While the pathophysiological mechanisms underlying morbidity and mortality in polydrug OD are not fully understood at the clinical level [10,36,37], it is possible that the risk of cardiac arrhythmia could be prominently increased

after dual exposure due to the concomitant respiratory depression and hypoxia caused by MOR agonists [22,38]  and the increased myocardial oxygen demand caused by stimulants  [39,40].

Based on the state of the field, the main aim of this study is to determine the latest trajectory of OD caused by polydrug synthetic opioid and stimulant exposure, as this has not been directly examined in recent studies[41–43], based on national data from the United States Centers for Disease Control and Prevention (CDC).  A second aim of the study is to determine how the changes in polydrug OD mortality occurred based on major individual differences in variables such as sex and age, which we and others have shown to be highly relevant to this risk[6,41].

**Methods:**

This study used de-identified publicly available data on "multiple cause mortality", from the CDC WONDER platform for 2018-2024 (https://wonder.cdc.gov/mcd.html). The Institutional Review Board of the Icahn School of Medicine at Mount Sinai certified that this study is not considered Human Subjects Research, and is thus exempt from its review requirements. As part of confidentiality protections, data that were "suppressed" (due to n < 10 per cell) or deemed "unreliable" in CDC WONDER were excluded from analysis. Data for 2024 are considered provisional at the time of downloading (June 2025). The overall age range studied was 15-74, due to low prevalence at younger and older ages. This observational study followed STROBE reporting guidelines (see supplement). The overall level of significance, alpha, was set at the p=0.05 level.

**Data set**

The main outcome variable was age-adjusted death rate per 100,000 population. We examined ICD-10 codes for overdoses (unintentional X40-X44, suicide X60-X64, homicide X85, and undetermined intents Y10–Y14). Data were obtained for three drug categories: "other synthetic narcotics" ("synthetic opioids hereafter; this predominantly reflects fentanyl and its analogs, but also compounds from other chemical scaffolds; T40.4)[21,44], psychostimulants with abuse potential (which predominantly reflects methamphetamine but also includes its analogs; T43.6), and cocaine (T40.5). Data were stratified by sex for the main analyses. In follow-up comparisons we also examined the two largest racial groups (White and African American or Black) in stratified analyses for synthetic opioid and stimulant polydrug overdoses. A further follow-up also stratified six consecutive 10-year age groups (i.e., 15–24, 25–34, 35–44, 45–54, 55–64 and 65–74). When this age stratification was carried out, analyses were based on crude rates.

**Data analyses:**

Annual data were obtained initially for polydrug OD mortality caused by synthetic opioids and stimulants, by searching: "Other synthetic narcotics" (i.e., synthetic opioids, ICD-10 code T40.4) *AND* ["Psychostimulants with abuse potential" (T43.6), *OR* cocaine (T40.5)]; this latter composite category is termed "stimulants" hereafter, for brevity. The CDC WONDER platform does not have a "*NOT"* search function, therefore in order to examine OD that were caused by synthetic opioids *without* stimulants (and vice versa), we carried out the following re-calculations, based on a simple Boolean strategy:

***Group a) Synthetic opioids without stimulants*** = [Synthetic opioid] - [Polydrug Synthetic opioid + Stimulant]
***Group b) Stimulants without synthetic opioids*** = [Stimulant] - [Polydrug Synthetic opioid + Stimulant]

Whenever relevant, standard errors (SE) for rates/100,000 for Groups a) and b) above were calculated with a Poisson approximation: $SE = 100,000 / N_{Population} * \sqrt{[OD\ counts_{Group\ a} + OD\ counts_{Group\ b}]}$.

**Joinpoint Analysis:** Joinpoint Regression software (V 5.4.0)[45] from the National Cancer Institute was used to examine annual trends in log-transformed age-adjusted overdose mortality rates (per 100,000). The technique was used to determine trends across years in a data-driven manner, by detecting "joinpoints" when a significant change occurs. Jointpoint regression examines annual percent change (APC) in the rate of OD for consecutive years ($APC = ((Rate_{Year\ N} - Rate_{Year\ N-1})/Rate_{Year\ N-1}) \times 100\%$). Thus, a positive APC value indicates an increase in OD mortality over consecutive years, and a negative APC indicates a decrease. The joinpoint regression parameters were as follows: We set the maximum number of possible joinpoints=2, taking into consideration the number of years under study[46]. The first order autocorrelation option was used to account for dependence of time series data. The Bayesian Information Criterion was used to select the number of joinpoints (i.e., 0-2) in the optimal model. The empirical quantile method[47] was used to calculate 95%CI for the APC, with 5001 resamples and a seed=10000.

**Follow-ups and sub-group analyses:**

**a) Focus on the most recent data:** OD mortality rates in 2024, and annual percent changes in OD mortality in 2024 versus 2023 were initially examined, with 2-way ANOVA (sex X type of drug),  using US census division - level data, after examining normality with the D'Agostino-Pearson test and checking quantile-quantile plots (Graphpad Prism V10.5.0). These ANOVAs used the Greenhouse-Geisser correction for violations of sphericity. In order to examine if major sociodemographic variables and public health interventions[48] were associated with state-level annual percent change in polydrug OD mortality rates for 2023-2024, we carried out an ordinary-least squares multiple linear regression, with asymmetric profile-likelihood 95%CI for the parameters. The predictor variables were sex (with females as the reference category), and z-score transformed values for prescribed naloxone dispensing rate per 100 persons (2023 CDC data)[49], and the following major social determinants of health, based on state-level data from the US Census Bureau's American Community Survey from 2023[50]: median household income based on census, OD rates in 2023, %of population which is African-American or Black, and % of population without health insurance. Utility of simpler regression models was evaluated with the Akaike Information Criterion. In this analysis, data from the following states were excluded, due to data suppression or unreliable estimates: Hawaii, Montana, Nebraska, New Hampshire, North Dakota, South Dakota, Vermont and Wyoming.

**b) Stratification by age:** In a followup examining national data in 10-year age groups (overall age range 15-75), the above joinpoint procedure was also used for 2018-2024, examining crude rates.

**c) Stratification by race:** We carried out stratified joinpoint analyses as above, for the two largest racial groups in national data (African-American/Black and White).

**Results**

**Demographics and mortality rates:** Supplementary Table S1A-C shows the number of OD deaths caused by the drug types under study, together with crude rates and age-adjusted rates, stratified by sex and year. Overall, males had approximately 2-fold greater overdose rates compared to females across the three drug types causing the OD, and years under study.

**Joinpoint regressions of national data:** We first examined sex-specific trajectories with joinpoint regressions (Fig. 1 and Table 1), which yielded differences across drug type and sex. **Polydrug OD caused by synthetic opioids *and* stimulants:** In males, there was an initial increase in OD from 2018, with two joinpoints (2020 and 2023), followed by a decrease in 2024. In females, there was also an increase from 2018, with a single joinpoint in 2022. **Synthetic opioids *without* stimulants:** In males, there was an initial increase in OD from 2018, with two joinpoints (2020 and 2023), showing a period of relative stability (possible plateau), followed by a decrease in 2024. In females, there was also an increase from 2018, with a single joinpoint in 2021, and a decrease thereafter. **Stimulants *without* synthetic opioids:** For both males and females, there was only one joinpoint (2021), indicating an increase in OD mortality in 2018-2021, followed by a decrease in 2021-2024. Of note, the magnitude of the APC was smaller for stimulants *without* synthetic opioids, compared to the two other drug types, indicating relative stability across 2018-2024 of OD caused by stimulants without synthetic opioids, compared to the former two groups (see Fig. 1).

**Figure 1:** Age-adjusted overdose (OD) mortality rates / 100,000 census population for 2018-2024 for males

and females (A-B, respectively). *Note different Y-axis ranges in the two panels.* Regression lines are based on

optimal joinpoint regression results (see Table 2). Standard error (SE) bars typically fall within the symbols.

Filled symbols indicate the "joinpoints" for each type of overdose based on the optimal models (i.e., the year in

which a change in trend is observed). Full data are in Supplement Table S1A-C.

**Table 1:** Joinpoint regression optimal models in annual overdose mortality rates (per 100,000; age adjusted). Models illustrated in Fig. 2.

**Figure 2: A.** Age-adjusted overdose mortality rates in the most recent year (2024) in males and females, based on census division - level data. **B.** Annual percent change (APC) in 2024 versus 2023. Full data in Table S2A-C

**Overdoses mortality in the most recent year, 2024:** We followed up the above analyses with a focus on the last year available (2024; provisional data), using census division - level data (full data with individual census division in Table S2A-C). A 2-way ANOVA for 2024 (Figure 2A) showed main effects of sex and of drug type, and no significant sex X drug interaction. Tukey tests show that polydrug OD rates in 2024 were greater than those caused by the two other categories (which did not differ from each other). This finding held in both males and females.

**Examination of APC data for 2024 versus 2023:** There were greater decreases in OD mortality in the polydrug and synthetic opioid without stimulant groups, compared to the stimulant without synthetic opioid group (Fig. 2B). Thus, a 2-way ANOVA using census division-level data detected a significant main effect of drug type, but no effect of sex or sex X drug interaction (Fig. 2B). Post hoc Sidak tests show that there was a greater decrease in OD rates in 2024 vs 2023 for the polydrug OD, and synthetic opioid without stimulant groups, versus the stimulant without synthetic opioid group, both in males and females.

**Multivariable adjusted model for annual percent change in polydrug overdoses in 2024 versus 2023:** We then extracted state-level OD data (Table S3) and sociodemographic data (Table S4), and carried out a univariate Spearman correlation matrix (Table S5) for an initial univariate exploration. This was followed by a

multiple linear regression, with state-level APC data for 2024 versus 2023 as the outcome (e.g., Fig 2B), with a multiple linear regression, adjusting for sociodemographic variables. These predictor variables explained a substantial proportion of the variance in the outcome variable ($R^2$=0.36; df=79). As shown in Table 2, neither sex, state-level naloxone dispensing rates and OD rate at baseline (2023) were not significant predictors of APC. The adjusted p-value for sex was marginal (p=0.075), and in a follow-up simple linear regression, we again found a marginal effect of sex on this APC (p=0.1; not shown). However, greater household income, and greater %of persons without health insurance were positive predictors of APC (indicating lesser decreases in OD rates). Greater %African-American or Black population was a negative predictor of APC (indicating greater decreases in OD rates). Simpler models (e.g., without median household income), were less preferred, based on the Akaike Information Criterion (not shown).

**Table 2:** Multiple linear regression for annual percent change in mortality for polydrug OD from 2024 versus 2023, studying sex and state-level predictors.

| Variable | Beta Estimate | 95% CI (profile likelihood) | P value |
|---|---|---|---|
| Intercept | -31.72 | -35.29 to -28.14 | <0.0001 |
| Sex (Male; Female as reference | -8.405 | -17.67 to 0.86 | 0.075; NS |
| State-level naloxone dispensing rate/100 (2023) | -1.16 | -3.79 to 1.47 | 0.38; NS |
| State-level median household income ($) | 5.29 | 2.54 to 8.04 | 0.0003 |
| State-level % without health insurance coverage | 6.30 | 3.44 to 9.15 | <0.0001 |
| State-level %Population that is African-American / Black | -4.84 | -7.38 to -2.28 | 0.0003 |
| State-level OD rate/100,000 (2024) | 0.12 | -0.15 to 0.38 | 0.39; NS |

**Age stratification of polydrug OD mortality in 2018-2024:** We stratified crude mortality data in consecutive 10-year age groups (overall age range 15-74; Fig. 3), and carried out separate joinpoint analyses in males and females. There was a biphasic pattern of age-related mortality across the years, with relatively low levels in the youngest age group (15-24), increasing until age 35-44, and then declining gradually from 45-54 to 65-74; this overall pattern was observed both in males and females. Sex differences (OD mortality M>F) were generally observed at each age group, and across years. The number and years of joinpoints differed across males versus females, indicating sex differences in the trajectories of these polydrug OD. Full data and jointpoint regression results are in Table S6.

# Polydrug OD caused by synthetic opioids and stimulants: Sex-specific profiles by age group

**Figure 3:** Crude OD mortality rates / 100,000 for 2018-2024 for males and females across 10-year age groups, (A-F). Some standard error bars fall within the symbols. Lines are based on optimal joinpoint regression results; filled symbols indicate the optimal "joinpoints". Full data are shown in Table S6.

**Race stratification of polydrug OD mortality in 2018-2024:** We carried out sex-stratified joinpoint analyses for the two most prevalent race categories in national data (African-American/Black and White). Peak mortality occurred in 2022-2023. While there were greater peak OD rates of persons in the African-American/Black category versus white, the APC in 2024 versus 2023 were similar. For example, in males there was a calculated APC of -49% [95%CI: -20% - -71%] for persons in the African-American/Black category, and -42% [95%CI: -20% - -56%] in the white category (data not shown).

**Discussion**

Polydrug OD caused by synthetic opioids and stimulants have reached epidemic proportions in recent years[7,51]. In this national cross-sectional study, joinpoint regression was used to examine the trajectory of this polydrug OD mortality across 2018-2024, expanding from prior reports [43,52]. This analysis detected increases in polydrug OD mortality after 2018, until 2023 in males and 2022 in females, and declined thereafter. Focusing more directly on the most recent trends (i.e., 2024 versus 2023; Figure 2B; Table S2A), relatively large decreases were observed in this polydrug mortality (i.e., -36% and -31% APC in males and females, respectively). Similar decreases were detected in 2024 versus 2023 for OD caused by synthetic opioids *without* stimulants (i.e., -42% and -39% APC in males and females, respectively), whereas smaller changes were observed for OD caused by stimulants without synthetic opioids (i.e., -3% and -2% APC in males and females, respectively). This result suggests that recent decreases in OD mortality for these types of compounds may be due primarily to changes in exposure, and/or public health prevention and intervention strategies focusing on synthetic opioids [30,53,54]. For example, changes in the illicit market supply for synthetic opioids have been observed (e.g., dosage or purity of fentanyl) [16,55]. Enhanced prevention and intervention strategies also included information campaigns, broader availability of intranasal naloxone [56,57], expansion of availability of fentanyl test strips [58], community-based drug checking services [59,60], as well as increased emphasis on rapid initiation and/or referral for MOUD in emergency settings [61–63], and reduction in regulatory barriers to MOUD prescribing [30,33]. Different cohort studies show that MOUD (e.g., methadone or buprenorphine) results in significant protection from OD over prolonged time scales [29,64,65]. The fact that less robust changes are observed on OD mortality caused by stimulants without opioids may be

due to aforementioned lack of specific antidotes for stimulant OD, or due to potential differences in the populations who self-expose to opioids versus stimulants.

We and others have shown robust sex differences in synthetic opioid or stimulant OD, where males have greater mortality across jurisdictions and environments[6,9]. In this study, males had approximately 2-fold greater polydrug mortality than females overall, even across dynamic yearly trends in 2018-2024. Intriguingly, whereas rates of polydrug OD mortality differed in males versus females, an adjusted analysis did not detect sex as a significant predictor of *change* across years (i.e., APC in 2024 versus 2023), indicating that recent decreases in mortality did not differ in males versus females in this state-level analysis. However, the marginal adjusted p-value for sex (p=0.075) does suggest that future studies on this issue are warranted. In this adjusted analysis, we also found that the rate of prescribed naloxone dispensing[49] was not a significant predictor of these changes in the polydrug OD (of note these data did not include over-the-counter naloxone sales, to be examined in the future)[27,66]. Population-based data do indicate that large-scale distribution of intranasal naloxone can result in decreased OD [67,68]. Furthermore, it cannot be excluded that some layperson-administered naloxone reversals may go unreported [69], resulting in a potential underestimate of the impact of this intervention on OD mortality. Importantly, the adjusted analysis in this study did detect that a lesser decrease in these polydrug OD occurred in states that had a greater percentage of the population without health insurance, adjusting for household income. This result suggests that availability of continuing care is associated with better public health outcomes, even for acute emergencies such as OD.

Synthetic opioid or stimulant OD mortality has also been shown to differ by age, with peak mortality typically observed in mid-adulthood[6,41]. Overall, this study provides the first age stratification for national polydrug OD across 2018-2024, and shows large differences in mortality across the lifespan, with highest risk at ages 35-44, similar to a prior study for opioids and stimulants studied separately [6]. Nevertheless recent decreases in polydrug OD rates were observed even for this high-risk age group, based on joinpoint regressions. The reasons for this age-related profile in OD mortality are unclear, but may include the typical lifespan trajectory of illicit opioid or stimulant exposure, usually commencing in late adolescence and early adulthood, followed by years of greater disease severity and peak use [70], consistent with the mean age of persons presenting to emergency departments for such OD care [5,10]. Data in CDC WONDER do not provide the longer-term history of drug exposure prior to the lethal OD, therefore future studies have to explore

underlying mechanisms [71] for the age distribution in this OD mortality. Intriguingly, impulsivity and risk-taking in the general population are reported to peak earlier in the lifespan (e.g., prior to age 25) [72,73], therefore these neurocognitive features alone are not necessarily the main underlying factor for the observed peak ages for polydrug OD mortality.

Race is an important social determinant of health, including for risk of OD mortality[6,48]. In a follow-up, we found that while polydrug OD rates differed across persons in the  African-American/Black racial group versus those in the white group, there were similar annual percent changes (i.e., decreases) in 2024 versus 2023. This suggests that effective prevention, public health strategies and cascades of care can be effective across a broad range of communities and sociodemographic features [74,75].

Illicit drug markets and OD epidemiology can differ across countries [76]. For example, recent data from Canada (for 2018-2022) also find that fentanyl combinations with either cocaine or methamphetamine are the most common polydrug combinations observed in OD mortality [77]. However, it is unclear if a similar decrease in either opioid or stimulant OD (or their polydrug combination) has occurred in 2024 versus 2023 in Canada [77]. As synthetic opioids are potentially entering the illicit supply in several countries (e.g., in Europe and Australia), continued vigilance and localized public health interventions will be critical in the coming years [76,78,79].

**Limitations:** This national study from the UnIted States has considerable strengths, but some limitations need to be considered.

**A)** The ICD-10 category for synthetic opioids is thought to reflect primarily fentanyl and its analogs[4], but can also contain MOR-agonists from other chemical scaffolds, including nitazenes[44]. Also, we did not study other types of MOR-agonists available for analysis in CDC WONDER (e.g., heroin, methadone or prescription opioids), as these are causing OD at a substantially lower rate than synthetic opioids, in recent years[6,80]. **B)** The "psychostimulants with abuse potential" ICD-10 category may primarily reflect methamphetamine, but presence of other amphetamine analogs or stimulants cannot be excluded. Also, for simplicity, we examined compounds such as methamphetamine and cocaine together, but their pathophysiological effects are not necessarily identical[81,82]. **C)** The data for 2024 are considered provisional at the time of this submission. However, there is relatively high completeness in CDC WONDER data after 6 months of occurrence  [83], and

the data for this study were obtained after such an interval (i.e., in June 2025). There may also be potential under-reporting or mis-reporting of OD mortality in death certificates[84,85]. **D)** For simplicity and based on the categories available in CDC WONDER, we did not examine further polydrug patterns (e.g., including benzodiazepines, alcohol or xylazine)[86–88]. Future studies should determine whether some of these other substances are particularly associated with the synthetic opioid and/or stimulant OD yearly trajectories in national data.

**Implications and conclusions:** This study provides sex-specific national trajectories of mortality for polydrug OD caused by synthetic opioids and stimulants in 2018-2024, relevant to the national OD crisis. Overall, relatively large decreases in this polydrug OD mortality were detected in 2024 versus 2023, similarly for males and females. However, joinpoint regressions indicate that trajectories of polydrug OD mortality across the broader 2018-2024 time period were not identical across sex, for reasons that should be examined. Furthermore, we also found that OD mortality caused by opioids *without* stimulants underwent a similar recent decrease in 2024, consistent with recent reports[41]. However, considerably smaller changes occurred in OD caused by stimulants *without* synthetic opioids. In addition, our age stratification analyses also show that while decreases in polydrug OD mortality were observed across a broad age range (overall range 15-74), persons in mid-adulthood remain at highest risk[70,89,90]. Overall, despite these recent decreases, polydrug OD rates in 2024 are still greater than those for the two other groups studied here, indicating that development of targeted prevention and intervention strategies is a continuing need[13,20,91]

**Competing Interests:** The authors have no conflicts to declare.

**Author Contributions:**

**Concept and Design: ERB**

**Data acquisition:** publicly available de-identified data from CDC WONDER

**Analysis:** ERB

**Interpretation and writing:** All authors

**Funding:** The authors gratefully acknowledge funding from NIDA-NIH DA5U01DA053625 (ERB), 2R01DA048009 (AM), 1R01DA060914 (RZG), 5R01DA049547 (NAK, RZG). The funder had no role in the design, drafting or editing of the project.

**Data Availability Statement:** Overdose data analyzed herein are publicly available from the United States Centers for Disease Control and Prevention CDC WONDER platform (https://wonder.cdc.gov/mcd-icd10-provisional.html).

Naloxone dispensing rates from the CDC are publicly available from https://www.cdc.gov/overdose-prevention/data-research/facts-stats/naloxone-dispensing-rate-maps.html. Sociodemographic data are publicly available from the American Community Survey for 2023, from the United States Census Bureau (https://data.census.gov/)

**Figure Legends**

**Figure 1:** Age-adjusted overdose (OD) mortality rates / 100,000 census population for 2018-2024 for males and females (A-B, respectively). *Note different Y-axis ranges in the two panels.* Regression lines are based on optimal joinpoint regression results (see Table 2). Standard error (SE) bars typically fall within the symbols. Filled symbols indicate the "joinpoints" for each type of overdose based on the optimal models (i.e., the year in which a change in trend is observed). Full data are in Supplement Table S1A-C.

**Figure 2: A.** Age-adjusted overdose mortality rates in the most recent year (2024) in males and females, based on census division - level data. **B.** Annual percent change (APC) in 2024 versus 2023. Full data in Table S2A-C

**Figure 3:** Crude OD mortality rates / 100,000 for 2018-2024 for males and females across 10-year age groups, (A-F). Some standard error bars fall within the symbols. Lines are based on optimal joinpoint regression results; filled symbols indicate the optimal  "joinpoints". Full data are shown in Table S6.
