Title: Reduced Risk of Liver Related Events Among Patients Receiving Individualized

Nutrition-Focused Remote Care in the United States

Financial support and sponsorship: None. This study was a retrospective analysis of deidentified claims data

Conflicts of interest: SJA, PVS, and AJW are full-time employees of Virta Health, and have been granted stock options. All remaining authors report no financial or professional relationships that could be perceived as potential conflicts of interest related to the study's data, analysis, interpretation, or reporting.

Keywords: Nutrition, MASLD, MASH, NAFLD, NASH, remote care, liver related events

Abbreviations: T2D, type 2 diabetes; VINT, Virta Individualized Nutrition Therapy; UC, usual care; LRE, liver related event; MASLD, metabolic dysfunction–associated steatotic liver disease; MASH, metabolic dysfunction–associated steatohepatitis; PHTN, portal hypertension; HCC, hepatocellular carcinoma; BHB, beta hydroxybutyrate

Abstract

Background and Aims

Metabolic dysfunction–associated steatotic liver disease (MASLD) and its progressive form, metabolic dysfunction–associated steatohepatitis (MASH), lead to significant morbidity and mortality in adults with type 2 diabetes (T2D) and obesity. This study evaluated whether participation in an individualized, nutrition-focused telemedicine care model emphasizing carbohydrate reduction (Virta Individualized Nutrition Therapy, VINT) was associated with reduced onset of MASLD, MASH, and advanced liver disease.

Approach and Results

Adults with T2D, prediabetes, overweight, or obesity who enrolled in VINT (2015–2024) were identified in the Komodo Healthcare Map and matched 1:1 to usual care (UC) controls (n = 5,031 per group). Using three complementary analytic approaches, incidence and time-to-event analyses were performed for new-onset liver disease. Across all strategies, VINT participants consistently showed lower incidence of any liver-related diagnosis (27.8 vs 42.8 per 1,000 person-years; HR = 0.61, p < 0.001), MASH and beyond (4.2 vs 10.7; HR = 0.38, p < 0.001), advanced liver disease (2.8 vs 8.7; HR = 0.33, p < 0.001) and any liver complications (2.0 vs 7.7; HR = 0.25, p < 0.001). VINT participants who lost ≥15% body weight was at lower risk of new-onset liver disease (21.2 vs 31.8 per 1,000 person-years; HR = 0.66, p = 0.02) compared to VINT participants who lost less weight.

Conclusions

Participation in individualized nutrition-focused telemedicine care was associated with significantly lower incidence and risk of new-onset MASLD, MASH, and advanced liver disease. These findings support lifestyle-first interventions that is potentially scalable to reduce liver disease burden in adults with T2D and obesity.

HEPATOLOGY

Plain Language Summary

People with type 2 diabetes and obesity are more likely to develop liver conditions such as metabolic dysfunction–associated steatotic liver disease (MASLD) and metabolic dysfunction–associated steatohepatitis (MASH), which can progress to cirrhosis, decompensation or liver cancer. This study examined whether a nutrition-focused remote care program could help prevent these liver diseases. The Virta Individualized Nutrition Therapy (VINT) program uses telemedicine and personalized, carbohydrate-reduced nutrition to support long-term weight loss and metabolic health. Using health claims data, researchers compared more than 5,000 participants in the VINT program with matched individuals receiving standard of care. Those in the VINT group had significantly fewer new cases of MASLD, MASH, and advanced liver disease. Participants who lost 15% or more of their body weight were especially protected. These findings suggest that individualized, nutrition-based remote care can help prevent liver disease in people with type 2 diabetes and obesity.

Introduction

Metabolic dysfunction–associated steatotic liver disease (MASLD) and its more progressive form, metabolic dysfunction–associated steatohepatitis (MASH), are increasingly recognized as major public health concerns in the United States and globally. Recent data indicate that MASLD affects approximately 30–35% of U.S. adults, with prevalence rising to 60–70% among individuals with type 2 diabetes or obesity (1–3). Modeling studies suggest that up to 20% of individuals with MASLD will progress to MASH, corresponding to an estimated 15 million U.S. adults at risk for cirrhosis, liver failure, hepatocellular carcinoma (HCC), and cardiometabolic complications (4). The global economic burden is substantial, with a recent analysis estimating that the clinical, humanistic, and economic impact of MASH exceeds $300 billion annually across major countries, underscoring the cost of inaction (5,6). These data are consistent with recent reviews identifying MASLD as a growing global epidemic and one of the leading causes of chronic liver disease worldwide (7,8).

Weight loss of ≥7–10% of body weight is strongly associated with histologic improvements in MASLD/MASH, including resolution of steatohepatitis and regression of fibrosis (9). Accordingly, current guidelines emphasize intentional weight loss as the cornerstone of therapy for MASLD/MASH (10-13). Pharmacologic therapies such as resmetirom (14) and semaglutide (15) are now FDA-recommended options for MASH treatment; however, intentional weight loss remains the primary and most consistently effective strategy for MASH resolution and fibrosis improvement, including when achieved through agents like semaglutide.

The Virta Individualized Nutrition Therapy (VINT), which delivers telemedicine-based remote care, health coaching, and carbohydrate-reduced nutrition therapy with an emphasis on

nutritional ketosis, has demonstrated durable weight loss and metabolic improvements across type 2 diabetes, prediabetes, and overweight/obesity populations in both clinical trials and real-world settings (16-20). Post-hoc analyses of the clinical trial data further revealed significant improvements in liver health, including normalization of alanine aminotransaminase (ALT) in 61% of those with elevated baseline values, reductions in aspartate transaminase (AST) and alkaline phosphatase (ALP), and improvements in surrogate MASLD markers. 20% fewer participants met criteria for suspected steatosis and 15% fewer classified as not having suspected fibrosis after one year (21).

A reduction in new-onset liver-related events (LREs) is the endpoint established by the FDA to support full approval for medications such as resmetirom or semaglutide, which are currently only conditionally approved. To address this gap, we analyzed claims data to assess the incidence of new-onset MASLD, the development of new-onset MASH (including cases that may have progressed from a prior MASLD diagnosis), and advanced liver disease among patients enrolled in VINT. For this purpose, we leveraged ICD-10 diagnostic codes to identify clinically meaningful endpoints at the population level.

Materials and Methods

Data Source

This study used data from the Komodo Healthcare Map™, a nationwide U.S. commercial administrative claims database capturing pseudonymized medical, pharmacy, and laboratory claims from a large insured population (22). Tokenized demographic records generated via privacy-preserving encryption were linked to enrollment, follow-up, and corresponding claims data for treated participants. A control population of 2.39 million individuals from the same

database was used to create the matched control cohort. The August 25, 2025 dataset iteration was analyzed within Sentinel, Komodo Health's secure real-world evidence platform.

Study Population, Intervention, and Medication Management

The analysis included adults (≥18 years) with type 2 diabetes, prediabetes, overweight, or obesity who enrolled in the Virta Individualized Nutrition Therapy (VINT) program for diabetes reversal or weight loss between August 2015 and September 2024 and remained enrolled for at least one year. Individuals with contraindications to nutritional ketosis (e.g., type 1 diabetes, active malignancy, pregnancy) were excluded. Full eligibility criteria and intervention details are provided in the Supplementary Methods.

VINT is a fully remote continuous care model combining individualized nutrition therapy, protocol-guided medication management, and health coaching via telemedicine. The dietary approach emphasizes individualized carbohydrate reduction to achieve nutritional ketosis (target β-hydroxybutyrate 0.5–3.0 mmol/L), moderate protein intake (~1.2–1.5 g/kg ideal body weight/day), and dietary fat to satiety, with a focus on whole, minimally processed foods. Participants receive structured education and ongoing real-time support from licensed medical providers and health coaches.

Medication adjustments were managed by VINT clinicians to ensure safety during carbohydrate reduction, with early dose reductions for hypoglycemia-prone agents (e.g., insulin, sulfonylureas) and individualized titration of other therapies as indicated. Biomarkers, including blood glucose, BHB, and body weight, were monitored daily at initiation, particularly during the

first three months, and subsequently tailored to participant preferences and tolerance, with treatment decisions guided by these data and clinician oversight.

Claims Analysis

For the claims-based analyses, both VINT participants and controls were required to have continuous medical and pharmacy claims coverage defined as no gap greater than 30 days for at least one year prior to the enrollment or index date and at least six months after. Control participants were assigned a randomly generated index date aligned with the distribution of enrollment dates in the VINT cohort to ensure temporal comparability. Baseline measures included in the matching encompassed demographic characteristics (age, sex, and race/ethnicity), clinical comorbidities, medication use, and healthcare costs. Comorbidities were identified using International Classification of Diseases, Tenth Revision, Clinical Modification (ICD-10-CM) codes appearing in either primary or secondary positions within medical claims (see Supplementary Table S1). Several liver conditions were excluded at baseline before matching (details in the supplementary method and Supplementary Table S1). Individuals with MASLD, MASH, and fibrosis were retained to allow evaluation of new-onset and progression outcomes within these at-risk populations. Medication classes assessed at baseline and follow-up are detailed in Supplementary Table S2.

Study Outcomes

The primary composite outcomes were defined as the time to new onset of any liver related diagnosis, MASH and beyond, advanced liver disease and advanced liver complications (Table 1 for details).

"New onset" was defined as the first occurrence of the outcome after the index date among participants who met the strategy-specific baseline inclusion criteria. Follow-up was limited to 5 years and was right-censored at the time a liver-related event occurred, at the end of the closed claims period, or at the study end date if no outcome occurred.

Analyses were conducted using three complementary analytic strategies to assess robustness and consistency. Analytic strategy 1 (incident disease cohort) excluded participants with baseline MASLD, MASH, or fibrosis and evaluated all three composite outcomes: any liver-related diagnosis, MASH and beyond, and advanced liver disease. Analytic strategy 2 (incident disease and potential MASLD progression cohort) excluded participants with baseline MASH or fibrosis (allowing baseline MASLD) and evaluated two composite outcomes: MASH and beyond, and advanced liver disease. Analytic strategy 3 (incident disease cohort with maximally restricted baseline) excluded all participants with baseline evidence of liver disease defined as MASLD, MASH, fibrosis, or findings suggestive of liver disease based on imaging, biopsy, or elastography procedure codes and evaluated the any liver-related, MASH-and-beyond and advanced liver disease composite outcomes. For the MASH-and-beyond, advanced liver disease analyses and liver complications, other liver-related diagnoses identified during follow-up (e.g., MASLD, abnormal liver imaging, or inflammatory liver disease) were not counted as events, ensuring a clean assessment of the prespecified composite endpoints.

Secondary outcome analyses were restricted to the VINT cohort. We evaluated whether categorical clinical variables including mean BHB level over 6 months ($\geq$0.3 vs <0.3 mmol/L and $\geq$0.5 vs <0.5 mmol/L), 6-month weight change ($\geq$10% loss vs <10% loss and $\geq$15% loss vs <15% loss), and HbA1c change at 1 year (or 6 months if 1-year data were unavailable; $\geq$0.5 percentage point reduction vs <0.5 point reduction or any increase) were associated with the

primary composite outcome of new onset of any liver related diagnosis, as defined in analytic strategy 1.

Exploratory outcomes characterized healthcare utilization and liver-specific procedures (e.g., ultrasound, elastography, CT/MRI, biopsy), comparing intervention participants with matched controls. For the MASLD, MASH, and fibrosis subgroups, we also conducted a descriptive evaluation of concomitant pharmacotherapy among participants with evidence of disease at baseline or who developed MASLD or MASH during follow-up. Medication classes were defined a priori and included metabolic and liver-directed therapies (e.g., GLP-1 receptor agonists, SGLT2 inhibitors, thiazolidinediones [pioglitazone], vitamin E, and statins).

Statistical analysis

This study was conducted and reported in accordance with the STROBE guidelines for observational research (23), with a completed checklist included in the Supplementary Material. A detailed description of the statistical analysis is in the supplementary methods. Baseline characteristics are summarized as mean (SD) for continuous variables and n (%) for categorical variables. Propensity scores were estimated using the logit of the predicted score, and 1:1 matching without replacement was performed. Exact matching was enforced on sex, age category, race/ethnicity, baseline liver condition indicators (MASLD, MASH, fibrosis), and medications with potential liver benefit, including incretin mimetics and SGLT2 inhibitors. Balance after matching was evaluated using standardized mean differences (SMDs), applying a 0.10 threshold for acceptable balance. Baseline covariates included demographics (age, sex, race/ethnicity), clinical conditions (type 2 diabetes, obesity, hypertension, hyperlipidemia, coronary artery disease, stroke, heart failure, chronic kidney disease stage, albuminuria,

smoking, alcohol-related diagnoses, and other cardiovascular disease), liver conditions, baseline

liver procedures, medication exposures (SGLT2 inhibitors, GLP-1 receptor agonists, statins,

insulin, sulfonylureas, DPP-4 inhibitors, and other liver-beneficial agents such as certain statins,

icosapent ethyl, omega-3 acid ethyl esters, vitamin E, α-tocopherol, gemfibrozil, and

fenofibrate), one-year pre-index utilization and cost measures, and geographic and

socioeconomic indicators (census region and area deprivation index quintile). Between-group

balance is described using SMD≤0.10 indicating adequate balance (no hypothesis tests for

baseline).

Primary composite time-to-event outcomes (definitions provided in *Study Outcomes*) were

analyzed using Cox proportional hazards models to estimate hazard ratios (HRs) and 95%

confidence intervals (CIs), comparing VINT participants with matched controls. For matched

analyses, stratified Cox models were applied by matched set, with robust standard errors

clustered on matched pairs to account for within-set correlation. All models were adjusted for

age, sex, and race/ethnicity. Extended models further adjusted for baseline diagnoses of type 2

diabetes and obesity, as well as follow-up use of cardiometabolic medications with potential

hepatic effects, including SGLT2 inhibitors, GLP-1 receptor agonists, statins, and other relevant

agents. Medication use was modeled both as categorical ever/never exposure and as continuous

proportion of days covered (PDC) to capture adherence.

Kaplan–Meier cumulative incidence curves were generated to visualize differences between

groups, with numbers at risk displayed at prespecified time points. Incidence rates were

calculated as events per 1,000 person-years. Absolute risk reduction (ARR) was computed as the

difference in incidence rates between the UC and VINT groups, and the number needed to treat

(NNT) was derived as the reciprocal of ARR (1/ARR), representing the number of individuals

who would need to receive VINT for one year to prevent one additional new-onset liver diagnosis compared with UC.

To assess the robustness of the findings, several sensitivity analyses were conducted (details in the supplementary method), advanced liver disease outcomes reassessed after a) excluding participants who developed other liver diseases during follow-up, b) survival model adjusted for healthcare utilization variables, c) a Fine Gray sub distribution hazards model, including death from any cause as a competing risk. Additionally, to further evaluate the consistency of all the primary results, analyses were performed using inverse probability of treatment weighting (IPTW) with stabilized weights. Weighted Cox proportional hazards models with robust variance estimators were then used to estimate hazard ratios (HRs) in the pseudo-population generated by IPTW.

Within the VINT cohort, secondary outcomes were assessed using multiple Cox models examining associations of weight loss, ketone exposure (BHB), and HbA1c change with incident liver disease, with additional Poisson and trend analyses across weight-loss categories. Exploratory analyses descriptively evaluated liver disease state transitions, liver-specific imaging/procedures, and medication use patterns in relevant subcohorts; full methodological details are provided in the Supplementary Methods.

All statistical tests were two-sided ($\alpha = 0.05$) with 95% confidence intervals (CIs), and analyses were conducted using R software (R packages used are listed in the Supplementary statistical method section).

Results

Study Participants Flow

Within the Komodo Sentinel claims environment, the initial study population included 78,755 individuals in the intervention cohort and 2.39 million in the control cohort (Figure 1). After applying the closed claims requirement, 10,170 intervention participants and 509,727 controls remained. Following the additional eligibility criteria of at least one year of continuous program enrollment, a minimum of six months of claims data follow up and after excluding some baseline comorbidities or conditions, 5,236 intervention participants and 200,778 controls met inclusion requirements and were retained for propensity score matching (Figure 1; Supplementary Table S3).

Baseline Characteristics

After 1:1 propensity score matching, the analytic sample consisted of 5,031 VINT participants and 5,031 controls (usual care, UC) (Figure 1; Tables 2 and 3), representing roughly 10% of the original dataset with similar tenure. To assess representativeness, the matched VINT cohort was compared with VINT participants excluded during screening. Baseline demographics and aggregated variables were broadly similar between groups, with most standardized mean differences (SMDs) ≤ 0.1. Minor imbalances were noted for race and ethnicity (SMD = 0.29) and program type (diabetes reversal vs. sustainable weight loss, SMD = 0.18) (Supplementary Table S4). Although these values exceed the stringent 0.1 threshold used in this study, they remain close to the more permissive 0.2 threshold that is sometimes applied in observational research to indicate acceptable balance. Post-matching, baseline characteristics were well balanced between VINT and UC across all covariates used in the matching (all SMDs ≤0.1) as well as most

comorbidities, clinical conditions, and medications not directly included in the matching process, except for follow-up duration (Tables 2 and 3). The matched cohorts had a mean age of 53 years, and the distribution of males and females was similar between the groups. At baseline, 5.1% of participants had MASLD/MASH (including fibrosis), 51% had type 2 diabetes, and 36% had obesity. Mean follow-up was 2.2 years in the VINT group and 1.9 years in the UC group. Although the mean follow-up duration was shorter in the UC group, survival analyses inherently accommodate unequal follow-up by using time-to-event with right censoring; thus, estimates remain unbiased under non-informative censoring. Furthermore, the selection of index dates for UC was aligned with the distribution of VINT enrollment dates. This approach ensured that seasonal patterns, temporal shifts, or year-specific effects were accounted for, as illustrated by the overlapping distribution of index dates between groups (Supplementary Figure 1).

Primary outcomes

Across all analytic strategies, VINT participants had consistently lower incidence rates of new-onset any liver-related diagnoses compared with UC. Under strategy 1, the rates were 27.3 vs 42.8 per 1,000 person-years (HR = 0.61; 95% CI 0.52–0.72; $p < 0.001$; Figure 2A), and under strategy 3, 27.4 vs 42.4 (HR = 0.62; 95% CI 0.52–0.73; $p < 0.001$; Figure 2B). These associations remained significant and of similar or greater magnitude after adjustment for medication use (Table 4). Based on incidence rates, the corresponding absolute risk reductions were approximately 15 fewer events per 1,000 person-years, yielding NNTs of 65–67 per year.

For new-onset MASH and beyond, incidence rates were consistently lower among VINT participants across all three analytic strategies: 4.2 vs 10.7 per 1,000 person-years (HR =

0.38; 95% CI 0.27–0.56; $p < 0.001$; Figure 2C) under strategy 1; 4.7 vs 11.5 (HR = 0.38; 95% CI 0.27–0.56; $p < 0.001$; Figure 2D) under strategy 2; and 4.2 vs 10.7 (HR = 0.37; 95% CI 0.25–0.55; $p < 0.001$) under strategy 3. These findings remained significant and directionally consistent following adjustment for medication use (Table 4). Based on incidence rates, absolute risk reductions ranged from 6.4–6.8 events per 1,000 person-years, corresponding to NNTs of 147–156 per year.

For new-onset advanced liver disease, VINT participants again demonstrated substantially lower incidence rates: 2.8 vs 8.7 per 1,000 person years (HR = 0.33; 95% CI 0.21–0.50; $p < 0.001$; Figure 2E) under strategy 1; 3.3 vs 9.5 (HR = 0.33; 95% CI 0.21–0.50; $p < 0.001$; Figure 2F) under strategy 2; and 2.9 vs 8.7 (HR = 0.30; 95% CI 0.19–0.49; $p < 0.001$) under strategy 3. The corresponding absolute risk reductions were 5.8-6.2 fewer events per 1,000 person years, yielding NNTs of 169-172 per year. As summarized in Table 4, the hazard ratios remained consistent after adjustment for medication exposure. Sensitivity analyses, including the exclusion of participants who developed other causes of liver disease during follow up and a Fine Gray subdistribution hazards model with death as a competing event, yielded similar results, further supporting the robustness of the findings for advanced liver disease (Supplementary Results). Another set of sensitivity analyses adjusting for healthcare utilization measures including outpatient costs, imaging frequency, laboratory testing, and evaluations per member per year produced results consistent with the primary analysis, reinforcing that the observed differences in advanced liver disease between VINT and UC were not attributable to differences in diagnostic activity or healthcare contact.

For new-onset liver complications, VINT participants again demonstrated substantially lower incidence rates compared with controls: 2.0 vs 7.7 per 1,000 person years (HR = 0.25; 95% CI 0.15–0.42; $p < 0.001$) under strategy 1; 2.4 vs 8.2 (HR = 0.27; 95% CI 0.17–0.45; $p < 0.001$) under strategy 2; and 2.1 vs 7.7 (HR = 0.25; 95% CI 0.15–0.43; $p < 0.001$) under strategy 3. The corresponding absolute risk reductions were approximately 5.6 to 5.8 fewer events per 1,000 person years, yielding numbers needed to treat (NNTs) ranging from 172 to 179 per year.

Diagnostic distribution at follow-up events (Figures 3A–3C; overall cohort by analytic strategy) showed UC had a greater proportion of advanced/later-stage liver diagnoses than VINT. In a separate subcohort with baseline MASLD/MASH/fibrosis and a follow-up date-coded diagnosis (Supplementary Table S5), most participants remained in the same diagnostic category, with higher stability in VINT (74.3%) than UC (69.6%); transitions to nonspecific or advanced diagnoses were infrequent and were similar or slightly lower in VINT.

Sensitivity analyses using IPTW-weighted Cox regression produced consistent results, which are presented in Supplementary Table S6.

Secondary and exploratory outcomes (see detailed results in the Supplementary Results)

In the VINT cohort, ≥15% weight loss was associated with a significantly lower risk of incident liver diseases, with a clear dose-response across weight-loss categories, associations were attenuated after medication adjustment (Figures 4A and 4B). Mean BHB and HbA1c reduction were not associated with incident liver disease. Exploratory analyses showed fewer liver-specific imaging/procedures in VINT versus usual care despite similar overall healthcare utilization, and medication use patterns were comparable between groups (Supplementary Tables S7 and S8).

Discussion

In this large US based matched cohort of adults at risk for MASLD, participants enrolled in the VINT program was associated with a lower risk of liver related events (Figures 5A and 5B), over five years. The NNT, approximately 170 to prevent one case of advanced liver disease and 180 to prevent one liver complication per year, highlights the meaningful population level impact achievable with individualized nutrition focused care. The VINT model, already deployed at scale for type 2 diabetes and obesity care in the United States, has immediate relevance for liver disease prevention. These findings support earlier MASLD identification and routine liver assessment in high-risk populations (24–26), integration of nutrition-aligned metabolic therapies with pharmacologic treatment, and policy efforts addressing upstream metabolic drivers such as food insecurity and equitable access to nutrition-centered care (27, 28).

Pharmacologic studies have also examined primary prevention of liver disease in diabetes populations. In a Veterans Health Administration cohort, GLP 1 receptor agonists were associated with lower risks of cirrhosis, its complications, and liver related mortality compared with DPP 4 inhibitors (29), and a Korean population study found that thiazolidinediones reduced risk of a composite MASLD or MASH outcome compared with DPP 4 inhibitors (30). While these findings highlight the role of medications in liver disease prevention, our results extend this evidence to a scalable, non-pharmacologic, lifestyle-based model. Although advanced liver disease events were infrequent, likely reflecting earlier disease stage, limited follow up, and the slow progression of MASLD and MASH (31, 32), VINT participation was associated with statistically significant reductions in new onset liver related events, including fibrosis, cirrhosis, portal hypertension, and related complications. These patterns parallel those seen in GLP 1

receptor agonist studies and emphasize the potential of early lifestyle interventions to alter liver disease trajectories in real world primary prevention settings. Importantly, medication use was balanced between cohorts, indicating that the observed benefits are independent of pharmacologic therapy.

Weight loss is a well-established therapy for improving MASLD, MASH, and fibrosis and remains central to all major guideline recommendations (9–13). VINT's continuous remote care model has demonstrated clinically meaningful and durable weight loss among adults with type 2 diabetes and overweight or obesity, with participants achieving and maintaining approximately 10–13 percent loss at two years in clinical trials (16–18) and 9–10 percent in real world settings (19, 20). Consistent with the landmark findings of Vilar Gómez et al., where ten percent or greater weight loss produced the highest rates of MASH resolution and fibrosis regression (9), our analysis showed that fifteen percent or greater weight loss was significantly associated with a lower risk of new onset liver disease. We also observed a clear dose response relationship between the degree of weight loss and both incidence and prevalence of liver disease. These findings align with a recent Cleveland Clinic cohort study of 110 patients showing that greater than five percent weight loss reduced the risk of progression to cirrhosis among individuals with obesity and MASH related F3 fibrosis (33). Collectively, these results highlight that both the magnitude and durability of weight loss are key to preventing liver disease progression at the population level.

Sustaining weight loss remains challenging due to limited time, resources, and nutrition support in routine care (34–38). In contrast, VINT has demonstrated long term durability, maintaining approximately 8 percent weight loss over five years in adults with type 2 diabetes

(39, 40) and 7–13 percent over four years in real world cohorts (20). Sustained weight loss is critical, as improvements in steatosis, MASH resolution, and fibrosis regression are often lost with weight regain. Importantly, VINT supports individuals using incretin-based therapies such as semaglutide, including deprescription pathways that help maintain long term weight loss, an important feature given the high real world discontinuation rate of GLP 1 therapies (41). Consistent with these findings, the Cleveland Clinic study similarly emphasized that weight loss greater than 5 percent must be sustained for at least one year to meaningfully reduce progression from MASH related F3 fibrosis to cirrhosis (33). Although ketone levels were not independently associated with reduced risk of new onset liver disease in this analysis, prior evidence indicates that nutritional ketosis supports long term adherence, weight loss durability, and may potentially contribute to MASLD and MASH improvement through multiple mechanisms including inhibition of the NLRP3 inflammasome, improved insulin sensitivity, reduced hepatic de novo lipogenesis, and epigenetic modulation (42–50). Longer term assessments of sustained ketosis are warranted.

Recently approved pharmacotherapies such as semaglutide and resmetirom represent important advances in MASLD and MASH management. Semaglutide produces robust weight loss and MASH improvement, while resmetirom provides direct hepatic benefits including histologic improvement in inflammation and fibrosis (14, 15, 51). Responses to resmetirom appear more pronounced when clinically meaningful weight loss is achieved (52), underscoring the additive potential of combining pharmacotherapy with structured lifestyle-based care. While these agents may ultimately be used together (53), embedding them within a lifestyle first framework could maximize clinical benefit (54) and potentially reduce long term reliance on dual therapy. Importantly, regulatory agencies require post approval evaluation of

pharmacotherapies on liver related events such as progression to cirrhosis, development of portal hypertension, hepatocellular carcinoma, liver related hospitalization, and liver specific mortality (55).

This study has several strengths, including its large real world matched cohort design with long term follow up and the use of multiple complementary analytic approaches to strengthen causal inference. The robustness of the findings was supported by consistent results across propensity score matching, inverse probability of treatment weighting, and three analytic strategies. Multiple sensitivity analyses further supported the reliability of the results. Excluding participants who developed other causes of liver disease during follow up yielded similar estimates for the advanced liver disease outcome. Adjusting for healthcare utilization measures produced consistent results, indicating that differences in liver outcomes between VINT and UC were not driven by variation in healthcare contact or diagnostic activity. To account for potential competing risk from mortality, a Fine Gray subdistribution hazards model confirmed that the cumulative incidence of advanced liver disease remained significantly lower among VINT participants even when death was included as a competing event.

Several limitations should be considered, with additional details provided in the Supplementary Discussion. MASLD identification at baseline and follow-up relied on ICD-10 codes due to the absence of anthropometric, laboratory, and imaging data in the claims-based Komodo database, precluding inclusion of measures such as weight, BMI, A1c, and lipid profiles. This may have led to under-ascertainment or misclassification of MASLD and MASH. The requirement for one year of continuous enrollment ensured data completeness but likely selected for individuals with stable insurance and greater healthcare engagement, as only 10–

15% of claims populations meet such criteria. VINT participants completing at least one year may also represent a more adherent subgroup, though this duration ensured sufficient exposure and follow-up. Lower rates of liver imaging among VINT participants likely reflect improved metabolic health rather than reduced surveillance, supported by sensitivity analyses showing comparable overall healthcare utilization, imaging, medication use, and evaluation frequency between groups. Mortality analyses were limited to all-cause deaths captured within the claims window, with no cause-of-death data available. The relatively short mean follow-up may have limited detection of advanced hepatic outcomes. Ketone exposure was assessed only in the first six months, potentially underrepresenting long-term nutritional ketosis. Finally, the predominantly commercially insured population and lack of income data may limit generalizability to lower-income or more diverse groups, although neighborhood deprivation was similar between cohorts and residual confounding cannot be ruled out.

Taken together, these findings demonstrate that participation in a structured, individualized nutrition program emphasizing carbohydrate reduction, nutritional ketosis, and continuous remote care was associated with a lower risk of incident MASLD, MASH, and advanced liver diseases including fibrosis, cirrhosis, portal hypertension, and related complications. To our knowledge, this is the first study to demonstrate that FDA recommended liver endpoints decrease and are achievable by non-pharmacological, non-surgical interventions. Collectively, the results support the potential for durable, lifestyle first models to alter the clinical trajectory of liver disease and reduce system level burden and highlight the need for future studies evaluating integration with emerging therapies, and long term cost effectiveness.

Table 1. Definition of Primary Composite Liver Outcomes

Outcome Category	Outcome Name	Composite Components Included	Clinical Rationale
Primary composite outcome	Any liver-related diagnosis	MASLD; MASH; liver fibrosis; cirrhosis; portal hypertension (PHTN); PHTN complications (ascites, varices, hepatic encephalopathy); hepatocellular carcinoma (HCC); or other abnormal liver imaging findings	Captures the full spectrum of incident liver disease from early to advanced pathology
Primary composite outcome	MASH and beyond	MASH; liver fibrosis; cirrhosis; PHTN; PHTN complications; HCC	Focuses on progressive liver disease beyond steatosis
Primary outcome of interest	Advanced liver disease	Cirrhosis; PHTN; PHTN complications; HCC	Represents severe liver disease progression and aligns with clinical trial and regulatory endpoints
Secondary composite outcome	Advanced liver complications	PHTN; PHTN complications (ascites, varices, hepatic encephalopathy)	Captures clinically significant complications driving morbidity and healthcare utilization

Note: Standardized mean differences (SMDs) were calculated using the TableOne package in R. For continuous variables, *p*-values were derived using the student's *t*-test when the normality assumption was met and the Wilcoxon rank-sum test otherwise. For categorical variables, *p*-values were obtained using the chi-square test or Fisher's exact test when cell counts were small. SMDs were computed as the absolute difference in means (or proportions for categorical variables) between groups divided by the pooled standard deviation. SMDs were calculated using both the TableOne and MatchIt packages to cross-validate covariate balance estimates. To evaluate covariate balance between matched groups, SMD ≤ 0.1 was used as the criterion for acceptable balance. Unlike *p*-values, which are influenced by sample size and may indicate statistically significant differences that are not clinically meaningful in large samples, SMD provides a sample size–independent measure of balance that quantifies the magnitude of difference between groups. Therefore, SMDs were used as the primary metric for assessing post-matching balance, while *p*-values were reported descriptively.

Abbreviations: UC, usual care; VINT, Individualized Nutrition Therapy (intervention) program

					+ Con PDC	0.27 (0.14-0.54)	

Note: Incidence rates are reported as events per 1,000 person years. Hazard ratios (HRs) and 95% confidence intervals (CIs) were estimated using Cox proportional hazards models. The "Demo" model was adjusted for age, sex, and race or ethnicity. The "+ Cat meds" and "+ Con PDC" models additionally adjusted for follow up medication use, including SGLT2 inhibitors, GLP1 receptor agonists, thiazolidinediones, statins, and other medications or supplements with potential liver benefits, modeled both as categorical ever or never use and as continuous proportion of days covered (PDC). All models also accounted for baseline diagnoses of type 2 diabetes and obesity. VINT refers to participants enrolled in the Individualized Nutrition Therapy program, and UC refers to usual care.

Analytic Strategy 1 excluded participants with baseline MASLD, MASH, or fibrosis and evaluated all composite outcomes. Strategy 2 allowed baseline MASLD but excluded baseline MASH or fibrosis and evaluated the MASH-and-beyond and advanced liver disease composites. Strategy 3 applied the most stringent baseline exclusions, removing all participants with any indication of liver disease (MASLD, MASH, fibrosis, or abnormal imaging/biopsy/elastography findings) and evaluated all composite outcomes. For the MASH-and-beyond, advanced liver disease, and

liver complications outcomes, other liver-related diagnoses identified during follow-up (e.g., MASLD, abnormal imaging, inflammatory liver disease) were not counted as events to ensure clean endpoint classification.

Figure Legends

Figure 1. Flow diagram depicting patient selection and attrition from the initial Komodo Healthcare Sentinel cohort to the final matched analytic sample.

Figure 2. Cumulative incidence curves for new-onset of all liver diagnoses under (A) analytic strategy 1 (incident disease cohort), (B) analytic strategy 3 (incident disease cohort with maximally restricted baseline), new-onset of MASH and beyond under (C) analytic strategy 1 (incident disease cohort), (D) analytic strategy 2 (incident disease cohort and potential baseline MASLD progression), new-onset of fibrosis, cirrhosis and/or portal hypertension (E) analytic strategy 1 (incident disease cohort), (F) analytic strategy 2 (incident disease cohort and potential baseline MASLD progression). Curves are displayed up to 4 years to aid interpretability, given the decreasing sample size late in follow-up, though all analyses were conducted using the full observation window with standard right-censoring.

Figure 3. Distribution of liver diagnoses observed after index or enrollment, compiled as events contributing to the primary composite outcomes under (A) Analytic Strategy 1, (B) Analytic Strategy 2, and (C) Analytic Strategy 3.

Figure 4. Dose-response relationship between the level of weight loss category in VINT versus UC in (A) incidence rates of any liver diagnoses onset (B) prevalence of any liver diagnoses during follow-up

Figure 5. Forest plot displaying hazard ratios (HRs) and 95% confidence intervals (CIs) for the association between participation in the VINT program and the incidence of (A) any liver-related

diagnosis (S1 and S3) and MASH and beyond under three analytic strategies (S1–S3) (B) advanced liver disease and liver complications under three analytic strategies (S1–S3)

Estimates are shown for three model specifications: the demographic-adjusted model ("Demo"), the model additionally adjusted for follow-up medication use ("Cat meds"), and the model adjusted for continuous proportion of days covered (PDC) with medications of potential liver benefit ("Con PDC"). Vertical dashed line at HR = 1.0 denotes no association. HRs < 1 indicate lower risk among VINT participants compared with usual care.

Figure 1. Flow diagram depicting patient selection and attrition from the initial Komodo Healthcare Sentinel cohort to the final matched analytic sample.

Figure 2. Cumulative incidence curves for new-onset of all liver diagnoses under (A) analytic strategy 1 (incident disease cohort), (B) analytic strategy 3 (incident disease cohort with maximally restricted baseline), new-onset of MASH and beyond under (C) analytic strategy 1 (incident disease cohort), (D) analytic strategy 2 (incident disease cohort and potential baseline MASLD progression), new-onset of fibrosis, cirrhosis and/or portal hypertension (E) analytic strategy 1 (incident disease cohort), (F) analytic strategy 2 (incident disease cohort and potential baseline MASLD progression). Curves are displayed up to 4 years to aid interpretability, given the decreasing sample size late in follow-up, though all analyses were conducted using the full observation window with standard right-censoring.

Data Availability

The datasets used in this study are not publicly available due to licensing restrictions. They were obtained under a commercial agreement with the data vendor and may only be accessed in accordance with the terms of that license.

Compliance with Ethics Guidelines

This study was deemed exempt from institutional review board (IRB) oversight because it utilized only retrospective, de-identified data and did not involve any direct interaction or intervention with human participants.

Reduced Onset of Liver Related Events with Individualized Nutrition-Focused Remote Care

VINT Participants (n=5031) vs matched control (n=5031)

38-57%
risk reduction
of all liver-
related
diagnoses

45-66%
risk reduction
of MASH and
beyond

67-71%
risk reduction
of advanced
liver disease

73-75%
risk reduction
of liver
complications

HEPATOLOGY
