Abstract

Tracheostomy is a life-saving procedure with complications often linked to suboptimal tracheostomy tube fit. Customised tubes could reduce these risks, but their development requires precise tracheal morphometric data. This study presents an automated workflow for extracting high-resolution tracheal measurements from CT scans, using 3D Slicer and a deep learning segmentation model (VISTA-3D). One hundred anonymised scans were analysed, with 90 included after exclusions. Automated measurements revealed average tracheal lengths of 66.1 ± 12.2 mm, anteroposterior dimensions of 16.2 ± 2.5 mm, transverse dimensions of 17.9 ± 2.4 mm, and maximum inscribed circle diameters of 14.1 ± 1.9 mm. Sex-specific differences were observed, with males exhibiting larger dimensions. The results align with existing literature, validating the automated approach. This method enables efficient, objective, and high-resolution morphometric analysis, supporting the development of demographic-specific tracheostomy tubes and improving pre-operative planning.

1. Introduction

Tracheostomy is a surgical technique in which an opening is created in the anterior wall of the trachea to facilitate airflow, often in the context of upper airway obstruction. It can be performed either via an open surgical technique or percutaneous techniques. Indications can be emergent, such as in cases of acute upper airway obstruction or traumatic injury, or elective, for example in cases of chronic aspiration, neurological conditions, or prolonged ventilator dependence [1].

Reported rates of complications vary greatly [2]. Complications of tracheostomy are generally divided into transoperative, early, and late. Transoperative complications include haemorrhage (most common), pneumothorax, injury to the recurrent laryngeal nerve, oesophageal perforation [3] and intraoperative loss of airway [4]. Loss of airway can result from obstruction of the tracheostomy tube lumen by blood clots or mucus.

A number of the late complications of tracheostomy arise from prolonged contact between the cannula and the tracheal wall, resulting in local trauma. Continuous friction is thought to cause granulation tissue formation, which can mature to form a fibrotic tissue layer, potentially resulting in tracheal stenosis. Tracheal stenosis resulting in lumen occlusion from 60-70% to total occlusion is particularly unfortunate [4]. Reported rates of clinically significant tracheal stenosis range from 3 to 12% [5]. The use of an oversized tube is a risk factor [5]. Malposition of the distal cannula tip against the posterior tracheal wall is another risk factor for trauma, a problem especially relevant in obese patients with increased neck thickness [3]. Chronic irritation can also lead to chondritis, weakening the tracheal rings and potentially resulting in tracheomalacia [3]. Among the most severe late complications is tracheo-innominate fistula, a rare but life-threatening event. It develops from local trauma to the anterior tracheal wall [6] and excessive cannula movement [3] leading to erosion into the innominate artery [3, 6]. The risk is particularly high when the tracheostomy is placed low (below the 3rd third ring) [3]. Another uncommon late complication is tracheo-oesophageal fistula, which likely occurs secondary to chronic trauma and ischaemia of the posterior tracheal wall [3].

Choice of tracheostomy tube size is important to mitigate the risk of aforementioned complications. Parameters to consider include tracheal diameter, tracheal length (proximal, i.e. depth of soft tissue in the neck and distal), and the angle at which the tube sits in the trachea [7]. How well tube

dimensions fit tracheal dimensions is therefore an important consideration, yet standard sizing assumes a relatively uniform anatomy despite the limited data available on normal adult tracheal measurements.

Ideally, each patient should have access to tailor-made tracheostomy tubes to ensure a perfect fit, and thus mitigate the risk of complications and increase the quality of life. Though many advances have been made in this direction, especially with the rise of additive manufacturing, mass adoption is still far ahead. A compromise in this regard is to offer a set of products tailored to specific target groups.

To identify these target groups and obtain the optimal parameters, a large number of tracheal measurements have to be made. CT scans provide a valuable source of information to obtain these parameters. Obtaining representative measurements for each target group, requires large numbers of measurements. Obtaining these measurements manually would be too resource intensive, hence this article explores how these measurements can automated.

2. Related work

Several factors influencing the dimensions of the trachea are sex [8, 9], the phase of pulmonary ventilation [10, 11], and tracheomalacia [11].

The work of Ebrahimian et al. focuses on tracheal dimensions in light of detecting tracheomalacia [11]. Their work compares manual and automated measurements during both phases of pulmonary ventilation. For manual measurements, they use the aortic arch as a reference for taking a single-section area measurement. For the automated measurement, they define average metrics for the anteroposterior (AP) dimension and surface area along the length of the trachea. They define the length of the trachea as the path from the thoracic inlet to a point slightly above the carina. For the normal patients the AP dimension ranged from $\approx$16–18 mm, and the surface area for this group ranged from 204–273 mm^2.

Kamel et al. makes a comparison between morphometrics derived from CT scans and cadaver data [9]. Based on the analysis of 60 CT scans, an average maximum AP dimension of 21.4 ± 3.2 mm is found and an average maximum transverse dimension of 25.7 ± 3.7 mm is found. In their study the patients scanned were required to hold their breath during scanning. Based on cadaver data from 10 subjects, an AP dimension of 20.8 ± 2.9 mm was

found for men, for women this was 15.5 ± 1.1 mm. The measured transverse dimension for men was 21.4 ± 1.6 mm and for women was 17.8 ± 1.5 mm.

Prince and Stark's main focus was relating the dimensions of the thyroid gland to the dimensions of the trachea [12]. The transverse dimension of the trachea was measured at the point were the thyroid had the largest transverse dimension. Their study examined 118 patients, with the majority being male (115). They found an average transverse tracheal dimension of 19.97 ± 2.37 mm.

The work of El-Anwar et al. measure the AP and transverse dimensions at the level of the thyroid gland [8]. They analysed 100 scans and found an average AP dimension of 16.56 ± 2.77 mm and an average transverse dimension of 15.5 ± 2.1 mm. Considering that this study was conducted in Egypt, genetic and geographic factors might impact the dimensions.

Green et al. present a small pilot study in which they used CT scans to preoperatively select the appropriate tracheostomy tube based on several key measurements [13]. In this study, 8 out of 11 patients had the correct tube size at first trial.

Most works still rely on manual workflows for morphometry of the trachea. This work fills this gap by presenting an automated workflow. Automatisation enables analysing large numbers of scans with little costs, and can provide fine grained morphometrics per demographic group. Furthermore, it enables a higher spatial resolution, a large number of measurements can be made which would otherwise be too time consuming. Higher spatial resolution means that the tracheal shape deformation along the trachea can be modelled.

3. Materials and methods

3.1. Data

The initial data set consists of 100 CT scans provided by the Medisch Spectrum Twente (MST), The Netherlands. An internal ethics committee of the MST granted permission to use the data. A selection of recent adult neck scans was provided by the radiology department. The data was anonymised before being exported, only the year of birth and sex remained in the metadata. A demographic breakdown of the subjects included in this research is given in Figure 1. The figure shows that the data is skewed towards males and towards a slightly elderly part of the population.

Figure 1: Demographic breakdown

3.2. Methods

The open source program Slicer was used [14] to automate the morphometric measurements of the trachea. This software was used because the processing steps available in the graphical user interface (GUI) can also be automated using Python code. The major advantage of this was that parameter settings and procedures could easily be evaluated visually in short iteration cycles. Thereafter these same steps can be added to the Python script to automate the workflow.

3.2.1. Segmentation

The first step was the conversion of the data from the Digital Imaging and Communications in Medicine (DICOM) format to the Neuroimaging Informatics Technology Initiative (NIfTI) format. This was done using the `dcm2niix` tool. This conversion was required as the segmentation model works with this format.

For the segmentation itself, the VISTA-3D segmentation model [15] was used. This segmentation model is a deep learning based foundation model capable of segmenting 127 classes from CT scan data, including the trachea and thyroid. The segmented trachea starts roughly at the thyroid cartilage

and includes part of both primary bronchi. The segmentation results are represented by an integer label per voxel.

Cleaning. The segmentation process is not perfect, hence some minor cleaning operations are required next. The cleaning operations make use of the segmentation toolbox [16] of Slicer. The regions at the extents of the trachea can contain small noisy blobs which are part of the segmentation. To remove these, we retain the largest blob only. In the case of the thyroid, the segmentation sometimes misses the region around the isthmus. This implies that the left and right lobe are not always connected, hence the strategy of retaining only the largest blob will not work. In this case the strategy is to remove all blobs below a certain volume threshold. The threshold parameter is defined in voxels. Based on the image spacing and a target threshold volume of 1 cm^3, the target number of voxels for the threshold is determined.

The segmented trachea sometimes contains small holes. These holes interfere with the determination of the cross sectional area. A morphological closing operation is performed using a 4 mm kernel to 'fill' these holes.

3.2.2. Centreline

After segmentation and cleaning, the next step is to extract the centreline of the trachea. This centreline is used to define at which positions the cross sectional areas of the trachea will be determined. The Vascular Modeling Toolkit (VMTK) extension of Slicer is used for determining the centreline and calculating the cross sectional areas. The VMTK was designed for analysing blood vessels [17], but also works well for other tubular structures such as the trachea. This toolkit is used to extract the centrelines of the trachea, and usually results in at least three lines. One for the main part of the trachea and two for the left and right parts of the primary bronchi. The longest line, representing the main part of the trachea, is selected for further processing.

To be able to derive some statistics of the cross sectional areas, it is important that they are all measured at the same location along the centreline. The measurements start at a point just above the carina and move upward towards the larynx. The extracted centreline is resampled so that the new control points have a fixed distance of 5 mm.

Centreline cut-off. The centreline extraction near the extents of the segmented trachea are not well defined. This is caused by an irregular segmentation at these areas. To compare individual trachea to each other, it is

(a) Oriented bounding box

(b) Plane

Figure 2: End-point landmark determination of tracheal centreline

important to define a consistent end-point along the centreline. A landmark used to determine this end-point is the plane which is perpendicular to the centreline and just touches the lowest part of the segmented thyroid. The normal of this plane is defined by the vector starting at the carina (index 0) and pointing to the point which is 20 mm away from the carina (index 4). The point used in describing the plane is the coordinate of the lowest part of the segmented thyroid (Figure 2b).

Using this plane, the end-point is defined as the last point of the centreline which still resides below the defined plane.An initial approach to determine this end-point was to use the lowest plane of the oriented bounding box (Figure 2a) of the segmented thyroid. This approach was not successful as the segmentation of the thyroid was not always complete.

3.2.3. Metrics

This section describes several of the metrics which are derived from the CT scans in an automated way. First is the cross-sectional area of the trachea at fixed intervals, thereafter the diameter of the maximum inscribed circle is described. At last the measurement of the anteroposterior and transverse dimensions are elaborated. Figure 3 provides an overview of how some of the metrics are determined. A cross section at each node of the centreline is defined, but in the figure only three are displayed as an example.

Figure 3: Centreline with examples of cross sections

Length. In our work we define the length of the trachea as the summation of all distances between control points of the centreline up to the previously defined end-point of the trachea (See Section 3.2.2).

Area. To obtain the actual cross sectional area, the internal workings of the toolkit define a cross cut perpendicular to the centreline at the position of the specified control point. The internal workings of the Slicer program can be called from within a Python script, hence it is possible to extract the cross sectional areas of the trachea in this way.

Maximum inscribed circle. The maximum inscribed circle (MIC) of is an important parameter as it directly relates to the diameter of the tracheostomy tube. The MIC is determined by first storing a binary image of the tracheal cross-section. Cross-sectional images are captured at each control point along the centreline of the trachea. After this a distance transform is applied to the binary images, the maximum value of this transform determines the radius of the maximum inscribed circle in pixels. The final step is a unit conversion from pixels to mm. This is done using the spacing information from the CT scan file.

Anteroposterior and Transverse dimensions. The same binary image can be used to determine the anteroposterior (AP) and the transverse (T) dimension

of the trachea. To determine the AP dimension, the binary image is summed in the first dimension and the maximum value is used. To determine the transverse dimension, the binary image is summed in the second dimension and the maximum value is determine once more. Conversion from pixel units to mm is once again done using the spacing information from the CT file.

4. Results

4.1. Exclusion

Out of the 100 subjects analysed, it was not possible to define a conclusive centreline cut-off point for four of the subjects. Out of these, two subjects has an insufficient complete segmentation of the upper part of the trachea which made it impossible to find the last point of the centreline which still resided below the thyroid plane. In one case the subject was intubated during the CT scan, which led to a corrupted segmentation of the trachea. In the other case there was a paratracheal air cyst [18] present which confused the centreline finding algorithm. These four subjects are therefore not used for further analysis.

Each of the scans has also been manually inspected to verify if a significant part of the main bronchi was present in the scan. Presence of these bronchi is necessary to determine the point just above the carina. In four cases the bronchi was not present, and in two cases the bronchi part was not sufficient enough for the centreline algorithm to work. These six cases have also been excluded from further analysis. The total number of subjects included for statistical analysis is therefore now 90.

4.2. Metrics

This section dives into the details of the following metrics of the trachea: length, area, minimum inscribed circle (MIC), the anteroposterior dimension and the transverse dimension.

4.2.1. Length

A histogram describing the trachea length is given in Figure 4. We see that the majority of the length measurements fall within the range 60–70 mm.

Figure 4: Tracheal length (mm)

4.2.2. Area

The statistics of the cross-sectional area of the trachea can be seen in Figure 5. The figure shows a box plot per 5 mm along the centreline of the trachea. The number above the median line indicates the number of samples which were available for calculating the statistic.

The general trend of tracheal area which can be seen in the figure is a large area at the start, then drops, and then finally increases slowly again. The drop in the beginning can be explained by the fact that this is area corresponds to the region of bifurcation.

Similar plots could have been made from the other measurements, but have been omitted for conciseness. Main goal of this figure was to show that it is possible to obtain high spatial resolution along the trachea. The other metrics are summarised in the next section.

4.3. Summary

Table 1 summarises some of the automated morphometrics of the trachea. These values were computed by averaging the values along the trachea. The findings from the table confirm prior observations that females have a smaller trachea in general.

Figure 5: Cross-sectional area of the trachea (mm^2)

Table 1: Morphometrics summarised

	All	Male	Female
Area (mm^2)	247.2±56.8	273.1±48.9	202.5±39.1
AP (mm)	16.2±2.5	17.3±2.0	14.1±2.0
Transverse (mm)	17.9±2.4	18.6±2.4	16.8±1.8
MIC diam. (mm)	14.1±1.9	14.9±1.6	12.7±1.4
Length (mm)	66.1±12.2	69.2±11.5	60.7±11.5

The automated cross-sectional area reported by Ebrahimian et al. ranged from 204–273 mm ^{2} for normal patients taking into account both pulmonary phases. For this same group of the patients the AP dimension ranged from ≈16–18 mm. Our values show a good resemblance to these existing numbers.

If we look at the average male transverse dimension of the trachea we find good alignment with the value reported by Prince and Stark [12]. They report a dimension of 19.97 ± 2.37 mm.

The length of the trachea reported here is significantly shorter compared to values reported by Kamel et al., whom report an average tracheal length of 102.8±9.9 mm. This large deviation can be explained by the fact that the work of Kamel uses the cricoid as a reference and we use the inferior of the thyroid as reference.

5. Discussion

Our study has a few limitations. First limitation is that the set of CT scans used for analysis does not represent a valid cross section of the entire population. Only patients with a medical indication will be scanned. Furthermore, the sex distribution of the sample set used is skewed towards males. In our case the sample set consisted of 57 males and 33 females.

A common landmark used with regards to tracheal measurements is the cricoid. In this work it was not possible to automatically determine this point hence the superior of the thyroid has been used. This especially affects the length measurement of the trachea.

6. Conclusions

Automated tracheal morphometrics has several benefits. First the objectiveness of the measurements improves. Secondly, large numbers of scans can be analysed effectively and efficiently. The time required for the automated Slicer program was around 60 s per scan. Automated morphometrics of the trachea enables targeted morphometrics for patients groups based on factors such as age, geolocation, and sex. These targeted morphometrics can be used by manufacturers of tracheostomy tubes define a limited product range which covers the needs of a large patient population. Automation also enables fine-grained metrics along the entire length of the trachea, which can be used for pre-operative planning. Such fine-grained insights would be too costly and time consuming to obtain if these were determined manually.

The results of this study are well aligned with the existing body of works related to tracheal morphometrics. It shows that proposed automated tracheal morphometrics method is a valid approach.

6.1. Recommendations

This work used a foundational model to perform the segmentation. This foundational model can be fine tuned to increase its accuracy of the classes of interest such as the trachea and the thyroid. Furthermore, it is worthwhile to explore if the cricoid can be added as new class to the model. The cricoid is a common landmark on which trachea morphometrics are based.

Currently the assumption is made that the trachea is perfectly oriented along the coronal plane as the patients are in the supine position during scanning. Further research can verify if this assumption is correct or that

the trachea needs to be aligned according to some other landmarks such as the vertebrae.

Currently the normal of the cross sectional plane is determined with a simple heuristic based on the control points of the centreline. A more refined method would be to fit a curve through the control points, this would ensure a more smoothed line which can be used for determining cross sectional planes. Benefit of this approach would be that less accurate control points will not influence the determination of cross sectional planes too much.

In our experience, automatisation of the Slicer program using Python had a steep learning curve. To make tracheal morphometrics available for a larger audience, a dedicated toolbox within the Slicer program is a viable option. For instance a valuable contribution could be a toolbox which automatically determines some key measurements of the trachea. These key figures can be used to select the appropriate tracheostomy tube size pre-operatively. Based on a small pilot study, Green et al. have already shown the feasability and benefit of this approach [13].

Another aspect which can be explored is the shape of the trachea. Stern et al. conclude that the shape of the trachea can vary greatly [10], thus it would be worthwhile to see if we can create an automated taxonomy for classifying tracheal shapes based on the analysis of a large corpus of CT scans.

Another important factor for correct fitting of the tracheostomy tube is the skin to tracheal wall depth. This measurement can also be automated in future work.

Declaration of generative AI and AI-assisted technologies in the manuscript preparation process.

During the preparation of this work the author(s) used Mistral AI in order to draft an abstract. After using this tool/service, the author(s) reviewed and edited the content as needed and take(s) full responsibility for the content of the published article.

Acknowledgements

We would like to thank the Slicer community, seldom have we seen such helpful (and civilised) responses on a discussion forum. We also thank the Medisch Spectrum Twente for providing the required data for our research and Atos Medical for their input. This work was supported by TechForFuture [grant number 2212].
