Abstract

Stroke can affect sensorimotor control, impairing balance and locomotion. These impairments increase fall risk, limit patient independence, and reduce quality of life. Here, we investigated how stroke affects bilateral coordination of soleus motor units during standing in individuals undergoing subacute rehabilitation. Fourteen individuals were recruited after admission for inpatient rehabilitation with sixteen age- and sex-matched controls. Both groups attended two sessions separated by one week, during which high-density electromyography (EMG) signals were recorded from soleus muscles while standing on force plates. Patients also performed the Berg Balance Scale (BBS). EMG signals were decomposed into motor unit spike trains, from which peristimulus time histograms and EMG waveform averages were computed in relation to peaks in center of pressure (COP). The amplitude of motor unit and EMG activity around COP peaks, directional tuning, and bilateral synchronization were estimated. Individuals post-stroke improved their BBS score between visits, but COP displacement and speed were still greater than controls. Soleus activity was tuned anteriorly in both control and non-paretic limbs, while it was tuned laterally in paretic limbs. Synchronization of soleus activity was also reduced in the paretic limb compared to controls. Furthermore, cross-correlation lag between limbs was greater in individuals post-stroke than in controls at visit 1, while it decreased to control levels at visit 2 (P=0.008). The decrease in lags was strongly correlated with improvement in BBS score (R=-0.94, P<0.001). These results highlight the importance of bilateral motor unit coordination in balance, which is disrupted in both spatial and temporal domains following stroke.

Key Points Summary

- We examined bilateral motor unit coordination during quiet standing in individuals in the early subacute phase following unilateral stroke, while previous works have focused on the chronic phase post-stroke.
- While the non-paretic limb of patients exhibited a spatial tuning of its activity oriented in the same direction as those of neurologically intact controls, the spatial tuning of the activity of the paretic limb was altered.
- Bilateral synchronization between soleus motor units was reduced in individuals post-stroke in comparison with neurologically intact controls.

57   • The level of bilateral synchronization between soleus motor units was associated with
58   balance function and improved after one week of inpatient rehabilitation.

Introduction

Stroke is a neurological deficit resulting from an acute focal injury to the central nervous
system caused by a vascular event (Campbell & Khatri, 2020). This injury dramatically impairs
cognitive and sensorimotor functions, with, for instance, half of stroke survivors exhibiting
balance impairments (Khan & Chevidikunnan, 2021). These impairments are characterized by
greater sway variability and greater speeds (Mizrahi *et al.*, 1989; Dickstein & Abulaffio, 2000;
Garland *et al.*, 2003; Garland *et al.*, 2007), primarily resulting from pathological neural
activation of postural muscles and their coordination. Garland and colleagues (2003; 2007), for
example, identified a reduced activation of the soleus muscle in the non-paretic limb using
electromyographic (EMG) recordings, with fewer differences between limbs observed
following rehabilitation. Furthermore, investigations into the bilateral coordination during
standing balance have revealed reduced synchronization between limbs in individuals post-
stroke (Arya & Pandian, 2014; Dietz & Schrafl-Altermatt, 2016; Yamanaka *et al.*, 2023).

These changes underlie alterations in the activation and coordination of motor units – the neural
structures that convert neural signals into motor outputs. In neurologically intact individuals,
motor units that serve the same function receive a high degree of common synaptic input from
both supraspinal and spinal circuits (Castronovo *et al.*, 2015; Negro *et al.*, 2016; Thompson *et
al.*, 2018), constraining them to coordinated activation and motor output. During unperturbed
standing balance tasks in neurologically intact individuals, motor units from the soleus are
tonically activated for weight support and show some degree of rate modulation. Motor units
from gastrocnemius medialis are recruited intermittently during larger balance adjustments and
gastrocnemius lateralis exhibit little activation (Vieira *et al.*, 2012; Héroux *et al.*, 2014; Pollock
et al., 2014; Hug *et al.*, 2021b; Cohen *et al.*, 2023b). Motor unit activation varies with the
magnitude and direction of postural sway, with soleus motor units demonstrating the greatest
modulation with center of pressure (COP) movements along the anteroposterior axis (Cohen *et
al.*, 2023a; Zaback & Thompson, 2026). Bilateral motor unit synchronization is present during
balance tasks in neurologically intact individuals (Gibbs *et al.*, 1995; Boonstra *et al.*, 2009).

In individuals post stroke, motor units in the paretic limb exhibit reduced discharge rates,
compressed rate coding, and altered recruitment patterns, and the extent of these changes are

moderately correlated with functional impairments (Kallenberg & Hermens, 2011; Chou *et al.*,

2013; McNulty *et al.*, 2014; Miller *et al.*, 2014b; Mottram *et al.*, 2014; Hu *et al.*, 2015; Li *et*

al., 2015; Hu *et al.*, 2016; Negro *et al.*, 2020; Beauchamp *et al.*, 2023; Tacca *et al.*, 2026).

During standing balance, a reduced correlation between bilateral motor unit discharge rates has

been observed in individuals with chronic hemiparetic stroke (Garland *et al.*, 2014), suggesting

they may arise from long-term adaptation in motor unit properties or numbers (Lukács, 2005;

Li *et al.*, 2011), or from the reorganization of synaptic inputs to these motor pools

(Karbasforoushan *et al.*, 2019; Beauchamp *et al.*, 2023). Whether these changes occur during

the acute phase of stroke, or emerge only over time, remains to be determined.

Here, we aimed to compare the activity of motor unit pools during a quiet standing balance

task in patients in the early subacute phase post-stroke and in neurologically intact controls.

We conducted two experimental sessions one week apart during inpatient rehabilitation. We

specifically investigated soleus motor unit activation during COP peaks, focusing on the

amplitude and directional tuning, as well as bilateral coordination of motor units. We

hypothesized that individuals post-stroke would exhibit greater differences in directional

tuning between legs, particularly in the paretic limb due to previously reported weakened

neural drive (Kallenberg & Hermens, 2011; McNulty *et al.*, 2014). Accordingly, we also

hypothesized that the bilateral coordination of motor units would be reduced in individuals

post-stroke compared to controls. Finally, we hypothesized that motor unit bilateral

coordination in individuals post-stroke would be related to the level of impairments quantified

with the Berg Balance Scale (BBS).

Materials and methods

Ethical approval and participants

14 individuals with subacute stroke admitted for inpatient rehabilitation were recruited for this

study (time since stroke to first session: 19±8 days, *n*=7 females; age=60.2±15.9 years,

height=171.0±6.1 cm, weight=77.6±16.3 kg, Table 1). The sample size for this study was

determined based on feasibility and was consistent with prior work [14 neurologically intact

participants (Zaback & Thompson, 2026)]. In the present study, we recruited a comparable

number of participants post-stroke (14). The sample size is also consistent with previous motor

unit studies in chronic stroke populations (Kallenberg & Hermens, 2009; Garland *et al.*, 2014;

Mottram *et al.*, 2014; Hu *et al.*, 2015; Li *et al.*, 2015; Hu *et al.*, 2016; McManus *et al.*, 2017; Murphy *et al.*, 2018; Negro *et al.*, 2020).

16 age- and sex-matched controls (n=8 females, age=61.2±14.7 years) were also recruited. Two additional controls were recruited to increase the likelihood of decomposing sufficient motor units to establish normative levels of motor unit function. Individuals post-stroke were included upon meeting the following criteria: 1) first stroke (ischemic or hemorrhagic); 2) supratentorial stroke location; 3) study completion within first six weeks post-stroke; 4) currently admitted to inpatient rehabilitation and enrolled throughout the entirety of the study (at least one week from baseline assessment); 5) score of less than or equal to 1 on question 1b (i.e., asking what month it is and the age of the participant) and 0 on question 1c (i.e., asking participant to open/close eyes or grip/release the therapist's hand) of NIH Stroke Scale for cognitive function (Brott *et al.*, 1989); 6) baseline visible muscle contraction of ankle plantarflexors; 7) no history of other neurological condition or injury that would impact motor recovery; and 8) no concurrent participation in other lower limb research studies that could confound results. The institutional review board of Northwestern University approved the protocol of this study (STU00214290), which followed the standards of the declaration of Helsinki. Participants (or a power of attorney) provided their informed written consent before baseline assessment. Consent and baseline assessment were completed in the first session for all participants. The second session replicated the baseline assessment one week later. All patients received standard physical therapy throughout the study as dictated by their clinicians. This consisted of a standard of 180 minutes of skilled therapy per day for five to six days per week, distributed between physical therapy (with a focus on high-intensity gait training), occupational therapy, and speech therapy.

Table 1: Participant Demographics

Stroke Participant	Age (yrs)	Sex	Stroke Type	Stroke Location	Hemi Side	Time Stroke to Admission (Days)	Time Stroke to Session 1 (Days)	Baseline BBS (out of 56)
1	62.0	Male	Ischemic	MCA	Left	16	24	48
2	75.7	Female	Ischemic	MCA	Right	6	18	28
3	71.1	Male	Ischemic	Thalamus	Right	4	11	34
4	56.6	Female	Hemorrhagic	BG	Left	10	15	29
5	19.0	Male	Hemorrhagic	FP	Left	10	15	5

Protocol

Participants stood on a split-belt treadmill (Woodway, USA) instrumented with force plates while standing shoulder-width apart with both feet aligned anteriorly and eyes open or eyes closed. Each trial lasted 30 seconds. All participants wore a harness for safety that did not provide support to the participant during standing, and a physical therapist provided assistance as necessary. The level of assistance was recorded for each task by an experienced physical therapist on the following scale: independent (0), supervision (1), touch assistance/supervision (2), touch assistance (3), partial assistance (4), and substantial assistance (5). Ground reaction forces were recorded from the instrumented treadmill at a sampling rate of 1500 Hz using a 16-bit A-D converter. Force and EMG data were synchronized using an external trigger (Micro1401, CED, UK) sent to both acquisition systems (EMG-Quattrocento; 400-channel EMG amplifier, OT Bioelettronica, Italy).

The BBS was recorded weekly as a part of standard clinical care, and results from the clinical assessments were obtained for this study.

Electromyographic Recording

Surface EMG signals were recorded from the soleus muscle of both limbs using two-dimensional adhesive grids of 64 electrodes (GR08MM1305, 13x5 gold-coated electrodes with one electrode absent on a corner; interelectrode distance: 8mm, OT Bioelettronica, Italy). The grids were positioned lateral to the Achilles tendon in the muscle shortening direction. The skin was shaved and cleaned with an abrasive pad and an alcohol wipe prior to placing electrodes.

162   A disposable adhesive foam layer held the grid of electrodes on the skin, and its cavities were
163   filled with conductive paste to improve the skin-electrode contact. Reference electrodes
164   (Ag/AgCl snap electrodes, Noraxon, USA) were placed over the patella, and a wetted strap
165   ground electrode was placed around the ankle. The EMG acquisition system recorded signals
166   in a monopolar montage at a sampling rate of 2048 Hz.

Data Analysis

Center of Pressure

169   The COP displacement was computed along the anteroposterior and mediolateral axes from
170   the split-belt treadmill and low pass filtered with a third order Butterworth filter at 5Hz. Root
171   mean square (RMS) COP displacement and COP speed were computed for the anteroposterior
172   and mediolateral directions as measures of balance variability and total displacement.

Bipolar EMG

EMG signals from each channel were visually inspected offline. Channels with significant
artifacts due to movements or disrupted electrode-skin contact were manually excluded from
further analyses. Across control and stroke participants, an average of 1.5 and 1.9 channels out
of 64 were removed, respectively. Bipolar EMG signals were computed by taking the
differential of every pair of artifact-free channels along the five columns, bandpass filtering
(second order Butterworth filter, 20-500 Hz cutoff frequency), and performing signal
rectification. The mean of all bipolar signals across the grid was computed and used for the
analyses on EMG amplitude.

EMG decomposition

Bandpass filtered monopolar EMG signals were decomposed into motor unit pulse trains using
a blind source separation algorithm (Negro *et al.*, 2016). Decomposition was run using the
peel-off option, and a silhouette value of 0.85 was used as a threshold to keep the valid motor
units pulse trains. Following the automatic peak detection identifying the discharge times, all
motor unit pulse trains were visually inspected and manually edited to remove false positives
(artifacts) and negatives (missed peaks) when necessary (Del Vecchio *et al.*, 2020; Hug *et al.*,
2021a; Avrillon *et al.*, 2024). Motor units were considered as duplicates when they shared at
least 30% of their discharge times with a tolerance of one data point (i.e., 0.5ms) (Holobar *et*
al., 2014). Motor unit activity and EMG signals were then downsampled to 1500 Hz to

maintain temporal alignment with force data. Muscles with less than three identified motor

units were excluded from further motor unit analyses.

Peristimulus waveforms and directional tuning

Previous work has demonstrated that reversals in anteroposterior COP movement are

accompanied by phasic changes in soleus muscle activation (Loram *et al.*, 2005; Zaback *et al.*,

2023). Therefore, by trigger-averaging motor unit and EMG activation in relation to prominent

COP peaks, it is possible to investigate the coordination of phasic neural drive to bilateral motor

unit pools in individuals post-stroke compared to neurologically intact individuals.

Anteroposterior and mediolateral COP time-series were extracted and used to segment the

motor unit discharge times and EMG time-series data. In neurologically intact individuals, the

standard deviation of the high-pass filtered (second order, 0.1 Hz cut-off dual-pass

Butterworth) COPs was used to set an individualized threshold for identifying prominent peaks.

However, as individuals post-stroke often display large balance adjustments that may skew this

threshold, standard deviation was calculated across segmented high-pass filtered COP data

(*window size* = 5s, *step size* = 1.25s, total of 24 segments/30s trial), and the lower 25th percentile

of these measures of variability was used to set an optimal peak detection threshold that would

be unaffected by the presence of aberrant fluctuations.

Windows of 3s centered over the events were used to segment motor unit discharge times and

EMG activity to analyze motor unit and muscle activations relative to COP peaks. Motor unit

peristimulus time histograms (PSTH) were computed relative to COP peaks in anteroposterior

and mediolateral positions. The PSTH was computed over 5ms bins with all motor unit firings

from a muscle pooled together and normalized by the number of peaks in each direction. Only

motor units that were discharging repetitively during the pre-stimulus period were included in

this analysis (>3 spikes without any interspike intervals>400ms). PSTH was baseline corrected

for each direction by subtracting the mean values between -1500ms and -1000ms. Similarly,

EMG signals were centered around COP peaks in the anterior, posterior, medial, and lateral

directions, and also baseline-corrected for each direction by subtracting the mean values

between -1500ms to -1000ms. To quantify the PSTH and EMG activation amplitude during

COP peaks in the four directions, the area under the curve from -400ms to 0ms relative to the

time of the COP peak was computed. This time was selected to quantify the activity that

resulted in the change in direction and the resulting COP peak, as done in previous works

(Zaback *et al.*, 2023; Zaback & Thompson, 2026).

This analysis was then extended to investigate how each motor unit pool activity is tuned with stabilizing torques oriented throughout the entire two-dimensional transverse plane. Using procedures described by Zaback and Thompson (2026), the two-dimensional COP data were iteratively rotated in 5° increments, generating a total of 72 unique signals representing the unidimensional movement of the COP across the transverse plane. The same peak detection algorithm described above was applied to each signal, and these event time stamps were used to generate 72 baseline-corrected PSTH and waveform-averaged EMG signals representing motor unit and muscle activation time-locked to stabilizing adjustment in different directions (Fig. 1). The area under the curve of the PSTH and EMG was estimated between -400ms and 0ms relative to the peak for each direction, and directional tuning curves were generated from the area values. The circular mean (Berens, 2009) of each tuning curve, which represents the direction of COP movement generally associated with the greatest muscle activation. To enable comparison between left and right limbs without introducing side bias, directional tuning curves from the left limb were reflected across the anterior–posterior axis. This transformation aligned both limbs to a common coordinate system such that anterior = 0°, posterior = 180°, medial = 270°, and lateral = 90° regardless of limb side (Fig. 1). A medial COP peak was defined as a peak directed toward the contralateral limb, whereas a lateral COP peak was defined as a peak directed away from the contralateral limb (i.e., toward the side of the limb of interest).

Contralateral-triggered motor unit and EMG activation

To assess bilateral coordinated activation between soleus muscles, phasic bursts of activity were identified from the cumulative spike train and EMG time series separately for each muscle. The timing and amplitude of activity observed in each muscle were then examined relative to the phasic bursts of the contralateral muscle.

The cumulative spike train of each soleus was computed by convolving the summed spike trains of all motor units within each leg with a 400ms Hanning window, and peaks in activity were identified using the same peak detection algorithm previously described to identify prominent peaks in COP time-series data. The 40th percentile of the standard deviation was used as a threshold instead of the 25th, utilizing a more selective criteria for the inherently greater variability of motor unit discharge and noisier EMG signals that has been reported in individuals post-stroke (Thomas *et al.*, 2002). PSTH of each limb were constructed in a 3s window relative to the peaks in the smoothed cumulative spike train of each limb and baseline

corrected. Similarly, rectified bipolar EMG signals were low-pass filtered (second order, 2 Hz

cutoff frequency, Butterworth), and the same approach was used to identify EMG time-time

series peaks and generate baseline corrected waveform averages in a 3s window relative to

peaks in the smoothed EMG. As previously done, PSTH and EMG amplitude was estimated

as the area under the curve in a window of -200ms to +200ms relative to the event. The

difference between contralateral and ipsilateral activation amplitude ($Amplitude_{contra}$ −

$Amplitude_{ipsi}$) was then computed, with a value of zero representing amplitude of contralateral-

triggered activation equal to ipsilateral-triggered activation. A value less than zero represents

a reduced amplitude of contralateral-triggered activation compared to ipsilateral triggered

activation.

Bilateral cross correlation

To further assess bilateral coordination of motor unit and EMG activations, cross correlations

were computed on PSTH and EMG waveform averages time-locked to anterior COP peaks

(0°). All signals were baseline corrected and smoothed with a Gaussian kernel of 50ms. The

maximum absolute correlation coefficient and the absolute lag at the time of the maximum

absolute correlation coefficient were computed for each trial with no maximum lag enforced.

To determine if there was significant coordination between limbs, the cross-correlation

coefficient was compared to a bootstrapped significance threshold that was computed by

shuffling the discharge times and EMG time-series and calculating the cross-correlation

coefficient. The 95th percentile of the bootstrapped cross correlation coefficients over 100

iterations was set as the significance threshold.

Figure 1: Experimental Approach. A) Anteroposterior (AP) center of pressure (COP), bipolar EMG signal, and decomposed motor unit (MU) firings were extracted during a 30s trial where participants stood on two force plates during quiet standing (as shown in C). Data were synchronized, peaks in the COP were identified, and for each COP peak, a 3s window of EMG and MU activity was extracted around the peak, as shown with the blue transparent rectangle. B) EMG and MU peristimulus time histogram (PSTH) waveform averages time-locked to COP peaks were computed. C) The time-locked waveform averages (EMG signals shown in the figure) were computed during COP peaks in the anterior, posterior, medial, and lateral directions within the transverse plane of axial rotation, as well as in 5° increments around the participant. D) Directional tuning curves were constructed across these 72 directions separated by 5° and the circular mean computed to determine the directional tuning of each muscle activity. The dashed line represents the 50th percentile of the area under the curve.

Statistics

For all analyses but the directional-tuning analysis, we used linear mixed effects models in SPSS 26.0.0.1. Normality of the data was assessed using the Shapiro-Wilk test, as well as by visually examining skewness, kurtosis, and histograms. For non-normal distributions, square root transformations were performed (West *et al.*, 1995; Kim, 2013). If the transformed data remained non-normal, a generalized linear mixed effects model was used. We compared the BBS of individuals post-stroke only across visits using a linear mixed effects model with Visit (1, 2) as a fixed effect and Participant as a random effect. We compared the RMS COP displacement (independently for different directions), COP speed (independently for different directions), and cross correlation coefficient and lag using a linear mixed effects model with Group (control, patient), Visit and Task (eyes open, eyes closed) as fixed effects and Participant and Assist level (scored 0-5) as random effect to account for the degree of independence in the tasks. We compared the amplitude of PSTH and EMG independently for each direction, as was done with the COP metrics, with Limb (control right, control left, paretic, non-paretic), Visit, and Task as fixed effects and Participant and Assist level as random effects. The random structure of all models included random slopes and intercepts to also account for between participant variability in the fixed effects. Ultimately, the model associated with the lowest Bayesian information criterion was retained for the analysis.

Circular statistical analyses were performed on the circular mean angle of PSTH and EMG using the circular statistics MATLAB toolbox (Berens, 2009). The Harrison-Kanji test, i.e., the equivalent of a two-way ANOVA for circular data, was used to identify significant effects of Limb, Visit, and Task. All combinations of two-way interaction were evaluated separately, as no three-way circular ANOVA was available. Where significant interactions were identified, the Watson Williams test, i.e., the equivalent of a one-way ANOVA for circular data, was used to investigate differences within each factor with significance level of 0.05 with a Bonferroni adjustment (i.e., α/k, where k is the number of contrasts).

We compared the difference in amplitude of contralateral- and ipsilateral-triggered activation with a linear mixed effects model with Limb (control left/right, control right/left, non-paretic/paretic, paretic/non-paretic), Visit and Task as fixed effects and Participant and Assist level as random effects. The selection of the random structure of the models followed the same procedure as above. Significance level was set at 0.05. Bonferroni corrections were used in post hoc tests for pairwise comparisons and Cohen's d effect sizes were reported with 95%

confidence intervals. Outliers exceeding three standard deviations from the mean were
excluded.

To determine the relationship between neuromuscular outcomes and functional balance in a
stroke population, a linear regression and a repeated measures correlation were performed to
examine how the change in BBS was related to the change in any outcome measure that
demonstrated a significant change across visits. For this analysis, only individuals with valid
data at both visits were included.

Results

Balance and center of pressure

Individuals post-stroke improved their BBS score from visit 1 (28.43 ± 12.19) to visit 2
(38.57 ± 8.71, $P<0.001$, $d=0.957$, 95% CI: [0.175, 1.739]; Fig. 2A). Twelve out of fourteen
participants improved greater than the minimal clinically important difference of five points
(Tamura *et al.*, 2022).

RMS COP displacement in the anteroposterior direction was greater in the stroke group
(13.48 ± 6.44mm) compared to controls (5.53 ± 2.60mm, $P<0.001$, $d=0.960$, 95% CI: [0.565,
1.355]) and lower at visit 2 (7.14 ± 4.27mm) compared to visit 1 (10.27 ± 8.53mm, $P=0.003$,
$d=0.414$, 95% CI: [0.004, 0.793]). Similarly, average COP speed in this direction was greater
in the stroke group (24.81 ± 12.57mm/s) than controls (13.48 ± 6.44mm/s, $P<0.001$, $d=0.771$,
95% CI: [0.383, 1.159]) and was lower at visit 2 (17.23 ± 10.21mm/s) compared to visit 1
(20.50 ± 12.21mm/s, $P=0.009$, $d=0.304$, 95% CI: [-0.072, 0.680]).

RMS COP displacement in the mediolateral direction was greater in the stroke group
(14.68 ± 11.77mm) than controls (2.74 ± 1.92mm, $P<0.001$, $d=1.365$, 95% CI: [0.949, 1.780]),
and greater with eyes open (9.37 ± 10.79mm) than eyes closed (7.40 ± 9.43mm, $P=0.009$,
$d=1.693$, 95% CI: [1.257, 2.128]). Average COP speed in the mediolateral direction was greater
in the stroke group (23.64 ± 18.33mm/s) than controls (5.77 ± 3.57mm/s, $P<0.001$, $d=1.242$, 95%
CI: [0.833, 1.650]), with greater speeds occurring at visit 1 (V1=16.61 ± 18.46mm/s,
V2=11.90 ± 12.01mm/s, $P=0.004$, $d=0.334$, 95% CI: [-0.043, 0.710]). Overall, individuals post-
stroke had greater COP displacement and speed than controls (Fig. 2B).

Figure 2: A) Berg Balance Scale (BBS) score out of 56. B) Anteroposterior (AP) and Mediolateral (ML) Root Mean Square (RMS) COP and COP Speed are displayed. * *P*<0.05.

High-density EMG decomposition

Motor unit yields are shown in Table 2. We excluded one control participant and three stroke participants from the motor unit analyses because no motor units were identified for any muscle.

Table 2: Motor unit yield across limbs, groups and visits

		Stroke		Control	
		Paretic	**Non-Paretic**	**Right**	**Left**
Eyes Closed	**Visit 1**	8.8±10.2	5.0±6.4	11.1±10.7	9.1±9.1
	Visit 2	6.1±6.9	8.7±8.0	11.9±8.8	12.8±8.4
Eyes Open	**Visit 1**	9.2±8.2	5.1±5.6	11.0±11.2	8.3±8.1
	Visit 2	6.4±7.0	7.0±7.2	13.6±9.2	12.3±7.4

Activation amplitude during COP peaks

The amplitude of PSTH and EMG during COP peaks was computed in the anterior, posterior, medial, and lateral directions (Fig. 3). For PSTH in the lateral direction, there was an effect of limb (*P*=0.016), with the amplitude in the paretic limb (0.063±0.091 pulses/peak) greater than in the left limb of controls (0.012±0.055 pulses/peak, *P*=0.016, *d*=0.786, 95% CI: [0.309,

1.263]). No other differences were observed between limbs (all *P*>0.287). There were neither

effects nor interactions in other directions (*P*>0.111).

For EMG in the medial direction, there was an effect of limb (*P*=0.018), with the amplitude in

the paretic limb (-0.018±0.061 µV/peak) lower than in the right limb of controls (0.002±0.020

µV/peak, *P*=0.042, *d*=0.557, 95% CI: [0.160, 0.953]) and left limb of controls (0.005±0.024

µV/peak, *P*=0.026, *d*=0.590, 95% CI: [0.185, 0.996]), but not the non-paretic limb (-

0.005±0.029 µV/peak, *P*=0.113, *d*=0.448, 95% CI: [0.037, 0.860]. There were neither effects

nor interactions in other direction (*P*>0.387). Collectively, these results indicate that the

activity of the SOL in the paretic limb is modulated with COP displacements along the

mediolateral axis.

EMG during COP peaks in anterior, posterior, medial and lateral directions. * *P*<0.05. V = Visit.

Directional tuning

To examine the directional tuning of the activity of the SOL, tuning curves were constructed from motor unit discharge activity (PSTH) and EMG amplitudes time-locked to COP peaks spanning the transverse plane (Fig. 4A). There was an effect of limb on the circular mean angle of these tuning curves derived from both PSTHs (*P*=0.006) and waveform-averaged EMG amplitudes (*P*=0.029). There were no effects of visit, task, nor interactions (all *P*>0.201). A Bonferroni correction was used to set the significance threshold at 0.008 (i.e., 0.05/6) for post-hoc comparisons with Watson-Williams tests.

In neurologically intact individuals, the activity of SOL in the control limbs was tuned anteriorly using both PSTH and EMG amplitude, in accordance with the previous work of (Zaback & Thompson, 2026). The same result was observed in the non-paretic limbs of individuals post-stroke. The activity of the SOL in the paretic limb, however, was tuned laterally and anteriorly (Fig. 4A). More specifically, for PSTH, the mean angle of the tuning curve was more lateral for the paretic limb (36.56±41.48°) than for the non-paretic limb (-4.17±45.39°, *P*=0.003, *d*=0.934, 95% CI: [0.400, 1.468]) and the right control limb (0.79±40.62°, *P*=0.004, *d*=0.874, 95% CI: [0.408, 1.340]). There was no difference with the left control limb (6.54±37.56°, *P*=0.012, *d*=0.770, 95% CI: [0.294, 1.247]). For EMG amplitudes, the mean angle of the tuning curve was significantly more lateral for the paretic limb (33.24±53.41°) than for the right control limb (2.27±39.90°, *P*=0.005, *d*=0.662, 95% CI: [0.267, 1.056]) and the left control limb (0.93±47.75°, *P*=0.008, *d*=0.640, 95% CI: [0.235, 1.044]). There was no difference with the non-paretic limb (8.67±59.53°, *P*=0.093, *d*=0.434, 95% CI: [0.025, 0.844]). Collectively, these results indicate that the activity of the SOL in the paretic limb was tuned laterally and anteriorly while the activity of non-paretic and control limbs were exclusively tuned anteriorly. This suggests that the greatest activation of the paretic limb occurred during lateral shifts toward the paretic limb.

Figure 4: Directional tuning of soleus activity. The first row displays directional tuning curves of
motor unit activity extracted from peristimulus time histogram (PSTH) from a control and a
participant post stroke. Additionally, the mean circular angle of the tuning curves extracted from
PSTH and EMG plots are displayed for each participant for each visit pooled across tasks, and the
mean per limb is displayed. To compare rotational responses across limbs, rotations were reflected
such that 90° always represents lateral tuning and 270° always represents medial tuning. * *P*<0.008.

Contralateral-triggered activation

To evaluate the synchronization between limbs, we averaged PSTH and EMG amplitudes for
each soleus around phasic bursts from the contralateral soleus (Fig. 5A, 5B). We then
calculated the difference between contralateral- and ipsilateral-triggered activation amplitudes:
zero indicates equal activation, and negative values indicate reduced activation of the limb
when peaks of activity are observed in the contralateral limb (Fig. 5C).

For PSTH, activations to contralateral peaks were different between visits (*P*=0.011) and limbs
(*P*=0.004), without interactions between visits and limbs (*P*>0.199). Specifically, the
difference in paretic limb activation during non-paretic limb peaks (-0.19±0.36 pulses) was
lower than the difference observed in the left control limb during right limb peaks (0.08±0.27
pulses, *P*=0.002, *d*=0.734, 95% CI: [0.234, 1.234]). The differences were not significant with

the non-paretic activation during paretic peaks (0.00±0.28 pulses, *P*=0.082, *d*=0.375, 95% CI: [-0.184, 0.934]), and with right control limb activation during left limb peaks (0.03±0.28 pulses, *P*=0.061, *d*=0.585, 95% CI: [0.091, 1.080]). Thus, activation amplitude of the paretic limb during phasic bursts of the non-paretic limb was substantially reduced, indicating that the paretic limb failed to coordinate reliably with the non-paretic limb. For EMG, there was no effect of visit, task, limb, nor interaction on the difference in amplitudes (*P*>0.245).

Figure 5: Contralateral-Triggered Activation. A) Control right (purple) and left (blue) and B) stroke participant paretic (red) and non-paretic (yellow) ipsilateral- and contralateral-triggered peristimulus time histogram (PSTH) waveforms during standing with eyes closed (visit 2 for the control and visit 1 for the stroke participant). The smoothed cumulative spike train (CST) is displayed

with the peaks shown with circles. As a guide to read these figures, for the top row of Panel A, the left
column is the CST of the control right limb with peaks identified. The middle column is the ipsilateral
activation or activation amplitude of the right limb during right limb peaks in CST. The left column is
the contralateral activation or activation amplitude of the left limb during right limb peaks in CST. C)
Difference between the amplitude of the contralateral (contra) and ipsilateral (ipsi) triggered
activation amplitudes. * $P<0.05$. R = Right. L = Left. Par = Paretic. Non = Non-Paretic. V = Visit. pps
= Pulses Per Second.

Cross correlation of motor unit and EMG waveform averages

Cross correlation coefficients between SOL activities of each limb and the corresponding
absolute lags were computed from PSTH (Fig. 6A) and EMG signals. All coefficients were
deemed significant compared to the 95th percentile of bootstrapped randomly shuffled signals.

For PSTH, there were no effects of group, visit, task, nor interactions on maximum absolute
coefficient ($P>0.763$). For absolute lag, a group*visit interaction ($P=0.037$, Fig. 6B) revealed
that absolute lag was greater for the stroke group at visit 1 (0.03±0.04s) compared to visit 2
(0.01±0.01s, $P=0.009$, $d=0.912$, 95% CI: [-0.009, 1.833]) and was greater for the stroke group
at visit 1 compared to controls (0.01±0.01s, $P=0.008$, $d=4.454$, 95% CI: [3.054, 5.853]).
However, absolute lag of the stroke group was no longer different from controls at visit 2
(0.01±0.01s, $P=0.491$, $d=0.319$, 95% CI: [-0.438, 1.077]), while absolute lag did not differ
across visits for controls ($P=0.912$, $d=0.021$, 95% CI: [-0.608, 0.651]).

For EMG, there was an effect of group ($P=0.005$, Fig. 6B), but no effects of visit, task, nor
interactions on maximum absolute coefficient ($P>0.170$). Controls demonstrated greater
correlation coefficients (0.79±0.19) compared to the stroke group (0.68±0.17, $P=0.005$,
$d=0.381$, 95% CI: [-0.017, 0.779]). The stroke group demonstrated higher absolute lag
(0.17±0.22s) than the control group (0.05±0.08s, $P=0.001$, $d=0.916$, 95% CI: [0.461, 1.371];
Fig. 6B).

Collectively, these results indicate greater lag, and therefore reduced coordination, between
limbs after a stroke. Importantly, when assessing lags on activity in PSTH, the stroke group
exhibited an improvement such that the bilateral synchronization improved from visit 1 to visit
2 to comparable levels to controls.

Figure 6: Lag between bilateral soleus activities. A) Bilateral smoothed peristimulus time histogram (PSTH) time-locked to anterior center of pressure (COP) peaks for a sample control and stroke participant from visit 1 and visit 2 during the eyes closed task. The graphical display of time lag is depicted, and the black line indicates the time of COP peak. B) Comparison of the maximum correlation coefficient and absolute time lag of smoothed PSTH and EMG between limbs. * *P*<0.05.

Regressions with changes in clinical outcomes

Only PSTH absolute lag demonstrated a significant longitudinal change for stroke participants. Therefore, the relationship between the change in PSTH absolute lag and the change in functional balance score (i.e., BBS score) for stroke participants was assessed via linear regressions. Data was averaged across tasks per participant as task effect was absent. A linear regression between the changes in lag between visits and the change in BBS score between visits revealed a significant negative correlation (R=-0.94, P<0.001). This was further

474   confirmed by a repeated measures correlation analysis with a significant negative correlation
475   between both variables (R=-0.78; P=0.002). Thus, an increase in BBS score was accompanied
476   by a decrease in lag (or an increase in synchronization).

Discussion

In this study, we quantified the bilateral coordination of soleus motor units during standing
balance tasks in individuals in the early subacute phase post-stroke. While clinical assessments
of balance and COP displacements and speed improved between visits, individuals post-stroke
continued to exhibit greater COP variability than controls. Furthermore, while control activated
the soleus in coordination, both spatially along the anteroposterior axis and temporally,
individuals post-stroke demonstrated differences in directional tuning and synchronization of
their soleus activity. While the non-paretic limb was also activated along the anteroposterior
axis, the paretic limb exhibited preferential activation along the mediolateral axis, and the two
limbs in turn also lacked temporal coordination. The synchronization improved with training,
and this improvement was shown to be related to improvement in functional balance,
emphasizing its importance to effective balance recovery.

Altered directional tuning of activity of the paretic limb

The soleus plays an essential role in balance, as its tonic activity with phasic modulation during
weight-bearing is critical for maintaining upright stance by counteracting the gravitational
torque acting on the center of mass (Loram *et al.*, 2004; Di Giulio *et al.*, 2009). Previous work
that has examined the directional tuning of the soleus, either through analysis of activation
amplitude in response to multi-directional perturbations or natural COP oscillations during
unperturbed standing, has shown that the soleus activity is primarily modulated with
movements of the COP or center of mass along the sagittal plane (Winter *et al.*, 1993; Winter
et al., 2003; Loram *et al.*, 2005; Ting, 2007; Zaback & Thompson, 2026). Cohen and colleagues
(2021; 2023a) further demonstrated that in neurologically intact individuals, some motor units
in the soleus and gastrocnemius medialis respond broadly across directions, while others show
direction-specific tuning. The results of this study corroborated previous findings, with motor
unit activity and EMG of neurologically intact individuals directionally tuned to anterior COP
peaks. During dual-legged standing, anteroposterior sway is controlled through modulation of
ankle plantarflexor and dorsiflexor torques, while mediolateral sway in neurologically intact

individuals is generally controlled by loading and unloading of the hip rather than by inverting and everting the ankle joints (Day *et al.*, 1993; Winter *et al.*, 1993; Winter *et al.*, 1996). This explains the anteriorly oriented tuning of the soleus in controls. It is noteworthy that the mean angles of the tuning curve observed here exhibited higher variability than those measured by (Zaback & Thompson, 2026) (SD: 37-47° vs. 17.7°). This difference may result from differences in demographics for the control group (8 males/females, mean age: 61.2±14.7 years here vs. 10 males; mean age: 29.9±7.2 years in Zaback and Thompson, 2026), as older individuals often experience impairments in balance control (Granacher *et al.*, 2011; Matsuda *et al.*, 2025). Another factor explaining this variability could be the duration of trials used to construct the tuning curves, which was limited here – compared to our previous study in neurologically intact individuals – due to the inability of our patients to maintain postures for long periods of time. However, the mean angles of control and non-paretic limbs align with the previous study (Zaback & Thompson, 2026), suggesting the robustness of the method with shorter trials.

While the non-paretic limb exhibited preserved directional control with anteriorly tuned activation, the paretic limb displayed an abnormal directional tuning, exhibiting modulation of activation along the mediolateral axis (Fig. 3) and greatest activation during anterior and lateral COP movement (~40° from anterior, Fig. 4). The abnormal modulation of paretic limb soleus activity along the mediolateral axis may be due to a couple of mechanisms. First, previous work has demonstrated slower generation of torque necessary to recover from perturbations when directed toward the paretic limb compared to perturbations directed toward the non-paretic limb or anteriorly (Palmer *et al.*, 2025), indicating a weakened response on the paretic limb. The nervous system, therefore, may prioritize activation of the paretic limb only for the most destabilizing perturbations, such as lateral shifts, for which the non-paretic limb cannot fully compensate – possibly as a result of compressed rate coding, impaired recruitment, or motor unit fatigue (Kallenberg & Hermens, 2011; Chou *et al.*, 2013; McNulty *et al.*, 2014; Miller *et al.*, 2014b; Mottram *et al.*, 2014; Hu *et al.*, 2015; Li *et al.*, 2015; Hu *et al.*, 2016; Negro *et al.*, 2020; Beauchamp *et al.*, 2023; Tacca *et al.*, 2026). Second, individuals post-stroke exhibit impaired proprioception, sensory processing, and spinal reflexes critical to balance control and rehabilitation after stroke (Wutzke *et al.*, 2013; Aman *et al.*, 2014; Chia *et al.*, 2019; Gorst *et al.*, 2019; Johnson *et al.*, 2025), which may result in abnormal directional tuning of the paretic limb. While individuals with chronic stroke exhibit increased stiffness of the gastrocnemius and soleus that could modify directional tuning and afferent feedback (Zhao *et al.*, 2009; Zhao

et al., 2015; Dias et al., 2019; Liang et al., 2024), these tissue mechanical changes may not have had enough time to develop in the acute sample recruited for this study (Lundström et al., 2010; Katoozian et al., 2018).

Reduced bilateral synchronization post-stroke

In addition to impaired spatial coordination of motor units and EMG, disrupted bilateral temporal coordination may also help to explain the asymmetrical control of the soleus and postural instability post-stroke. Previous work has shown that anterior sway induces greater common drive between bilateral soleus muscles compared to backward sway in neurologically intact individuals (Mochizuki et al., 2007), while greater instability is associated with increased lag and reduced correlation between bilateral soleus muscles (Promsri, 2022). In this study, cross correlation analysis revealed greater lag between limbs during anterior COP peaks in individuals post-stroke compared to controls. Interestingly, PSTH absolute lag decreased from visit 1 to visit 2, marking the only observed longitudinal improvement in neural metrics. No other longitudinal changes were observed, which may be the result of the small sample size and the large variability between participants. The physical therapist assistance may have also impacted the outcomes, but this was accounted for in the statistical tests, and the level of assistance did not change over time (average change: -0.43 ± 0.63 points out of 5, P=0.251). This change in PSTH absolute lag suggests a link between improvements in bilateral synchronization and balance recovery during early rehabilitation, but future studies with larger sample sizes will be necessary to corroborate these initial findings. Additionally, when evaluating activation amplitude during phasic peaks in the contralateral limb, there was a relative reduction in amplitude for the paretic limb compared to controls, further indicating impaired bilateral coordination.

These findings suggest potential mechanisms for impaired bilateral coordination. First, processing and transmission of proprioceptive information between limbs may be disrupted, resulting in the increased correlation lag between limbs and reduced amplitude during contralateral phasic activation. In neurologically intact individuals, when a vibratory stimulus is applied to one leg, the level of common drive between bilateral soleus muscles is reduced, suggesting that proprioceptive feedback not only plays a role in unilateral soleus modulation but also bilateral coordination (Mochizuki et al., 2007). Similarly, in the same study when triggering based on contralateral voluntary activation, a reduction in contralateral amplitude was observed. When triggering using contralateral non-noxious electrical nerve stimulation for

individuals post-stroke, a reduction in contralateral amplitude was observed when triggering
on the paretic leg due to disrupted sensory processing post-stroke (Dietz & Schrafl-Altermatt,
2016). This further supports the hypothesis that following stroke, processing of sensory
information used for bilateral motor coordination is impaired, potentially impairing the ability
of individuals to generate synchronous stabilizing torques.

Bulbospinal pathways, such as vestibulospinal and reticulospinal tracts, are important for
modulation of soleus motor unit activity in neurologically intact individuals (Monsour *et al.*,
2012), making their function critical for balance. However, a stroke may alter the bilateral gains
and descending commands of these pathways, which can have debilitating effects on motor
control and coordination (Marsden, 2005; Miller *et al.*, 2014a; Mccall *et al.*, 2017). Previous
research showed that activation of brainstem pathways following stroke via galvanic vestibular
stimulation led to hyperactive force responses on the non-paretic limb (Marsden, 2005),
suggesting asymmetrical brainstem activation. Interestingly, it has been demonstrated that
modification of balance may be mediated by a combination of central and peripheral systems,
where central structures may modulate feedback loops based on task demands (Welch & Ting,
2014). Therefore, impairments in descending commands and proprioception after stroke may
have contributed to the abnormal balance observed in this study. Future work is necessary to
provide a more complete understanding of the neural circuits underlying impaired balance post-
stroke and how they interact at the different levels.

Motor unit coordination predictor of balance function

In addition to characterizing deficits in neural coordination during the early subacute phase
post-stroke, we aimed to evaluate the relationship between changes in these neural measures
and functional recovery, as assessed by licensed physical therapists using the widely used
balance assessment, the Berg Balance Scale. A regression between the change in BBS and the
change in synchronization of motor unit activity (PSTH absolute lag) between visits was
assessed, as this was the only metric to demonstrate an improvement across visits. This analysis
revealed that a change in synchronization was strongly associated with a change in BBS score
($R=-0.94$; $P<0.001$), suggesting that individuals who improve their bilateral synchronization
also achieve improved functional balance.

Thus, PSTH-derived metrics may be considered as a biomarker when assessing patients'
control of balance. However, the application of such approaches is currently limited to high

quality recordings capable of extracting multiple motor unit firings in patients. For example, it is noteworthy that our regression analysis only included individuals with motor units extracted in both visits, with three individuals in the stroke group excluded from all motor unit analyses due to the inability to extract any motor units. The absence of extracted motor units may be explained by physiological factors, such as low muscle activation or reduced neural drive, but also poor signal quality, which are particularly present after stroke. Therefore, to extend the applicability of motor unit-based clinical analyses, future work must continue to improve HD-EMG sensors, extend investigations to intramuscular EMG, and enhance decomposition techniques to increase motor unit yields across wider populations.

The synchronous behavior of motor units may be facilitated by preserved neural pathways in the higher functioning individuals. Recent studies have investigated altered behavior of motor unit and how the altered behavior correlated with functional impairments (e.g., Fugl-Meyer, fatigue, walking speed) (Kallenberg & Hermens, 2009; Hu *et al.*, 2016; McManus *et al.*, 2017; Negro *et al.*, 2020; Li *et al.*, 2024; Tacca *et al.*, 2026). However, only Li et al. (2024) evaluated longitudinal relationships between motor unit number estimates/ F-waves and upper extremity Fugl-Meyer score, highlighting a critical next step in elucidating the neural mechanisms underlying the impaired motor control observed in this study. Future work should also combine recording modalities to evaluate changes in motor function at multiple levels (e.g., peripheral, spinal, brainstem, cortical) to more effectively map the altered neural networks responsible for post-stroke impaired balance.
