Abstract:

Background:

Population cancer screening detects the presence of early-stage disease rather than assessing future disease risk. We evaluated whether widely implemented cardiovascular disease (CVD) risk models can predict 10-year cancer risk, comparing them with the QCancer risk model.

Methods:

We evaluated four CVD prediction models: QRISK3, PCE, and SCORE2/SCORE2-OP. Models were recalibrated using 20% of the UK Biobank (UKB) cohort and tested in the remainder and in the Clinical Practice Research Datalink (CPRD). We gauged model performance by discrimination and calibration and evaluated feature importance.

Findings:

In UKB, the c-statistic for incident CVD ranged from 0·71 to 0·74 (2,790 events). All CVD models achieved a c-statistic of 0·63 for cancer (5,717 events) and had comparable discrimination to CVD for gastro-oesophageal, liver and biliary tree, laryngeal, renal tract, and lung cancers (c-statistic range: 0·70;0·81). The recalibrated CVD models showed near-perfect calibration (intercept 0·01, Q1;Q3 -0·05;0·03; slope 1·00, Q1;Q3 0·93;1·15). Performance in CPRD (393,560 cancer events) was similar: the median c-statistic was 0·01 higher (95%CI 0·00;0·02), calibration intercept was 0.06 higher (95%CI 0·02;0·17) and slope was 0·01 (95%CI -0·06;0·08) lower than in UKB. After age, smoking status and systolic blood pressure were the most influential predictors of cancer risk.

Interpretation:

Widely implemented CVD prediction models perform similarly to the less widely used QCancer model in the prediction of incident cancers. They may be used to inform cancer prevention and guide risk-stratified monitoring. Recalibrated models are available through an API.

Background:

Cancer and cardiovascular disease (CVD) are responsible for half of all deaths worldwide[1]. The global health burden of these conditions is increasing, with cancer deaths expected to rise by approximately 75% by 2050[1]. CVD and cancer share common risk factors, may co-occur, and are both potentially preventable via similar interventions. Addressing their modifiable risk factors is estimated to prevent over 75% CVD and 40% cancer diagnoses[2,3].

Despite these commonalities, early identification and intervention approaches differ. Risk models, such as QRISK3[4], are deployed to predict risk of CVD and as decision tools to commence medication for primary prevention. In contrast, for a limited range of cancers only (cervical, colorectal and breast), screening programmes use imaging or sampling to identify early disease. This targets people who benefit from cancer treatment but does not identify disease-free individuals who are at elevated risk of developing cancer in the future.

Clinical risk models that estimate future risk of cancer already exist (e.g. QCancer) but are not frequently used in practice[5]. In contrast, CVD models are widely used. We therefore set out to explore whether CVD prediction models could be used to additionally identify people at risk of developing incident cancers.

We compared the performance of four CVD risk models in the prediction of the 11 cancer diagnoses against which the QCancer prediction models were developed and added four cancer diagnoses that are associated with high morbidity and mortality (laryngeal, brain, melanoma, liver and biliary tree cancers). We also evaluated whether the CVD models could predict the joint risk of people developing cancer and CVD, differentiating between cancer diagnoses before or after a CVD event.

Methods:

Data resources

The UK Biobank (UKB) was used for the primary analysis, and the Clinical Practice Research Datalink (CPRD) Aurum database for external validation. The UKB recruited over half a million participants across the UK between 2006 and 2010, which we split into 20% training and 80% testing sets. CPRD provided longitudinal information on anonymised primary care records of 29,275,406 individuals in England from 1st April 1997 to 29th March 2021. These data resources have been described in detail previously[6,7].

Both UKB and CPRD linked to Hospital Episode Statistics (HES), primary care data, and Office of National Statistics (ONS) death registry records, with the UKB offering additional information from the National Cancer Registration and Analysis Service (NCRAS)(7). We also used data collected at UKB registration, such as information on demographics, lifestyle, self-reported information including from nurse-led interview, and clinical data such as blood pressure, BMI and biochemistry data. To focus on clinically relevant subset of participants, we excluded participants under 40 or greater than 84 years of age at the start date of our study (1st January 2011).

Outcome definitions

We defined CVD as the composite of coronary heart disease, ischaemic stroke and sudden cardiac death. The any cancer endpoint included all cancers except non-melanomatous skin cancers. The specific cancer types we considered were: colorectal and anal, pancreatic, gastro-oesophageal (any stomach cancer or oesophageal cancer), liver and biliary tree (any liver cancer or cancer of the bile ducts), prostate, breast ovarian, uterine, melanoma, brain and other intracranial cancers, oral, laryngeal, any blood cancer, renal tract (any kidney, ureter or bladder cancers); and lung cancers.

We considered the composite outcomes of any cancer, CVD or any cancer, and CVD and cancer. For participants who developed both CVD and cancer, we differentiated between CVD occurring after a cancer diagnosis, and CVD occurring prior to a cancer diagnosis. Finally, we included accidental injury as a negative control (see supplemental materials and Table S1 for the code lists used to define these outcomes). Prevalent conditions were defined as any diagnoses before or within one month of study start to accommodate recording delays(8).

Implementation of risk prediction models.

We calculated the predicted risk for all participants using the QRISK3, PCE, SCORE2, SCORE2-OP and QCancer models, applying the original model coefficients. We compared the predicted risk calculated by each model against the observed risk of each outcome at 10 years of follow up. The definition of the predictor variables for each model can be found in the supplemental materials and in Table S1. For composite outcomes without existing QCancer models (e.g., any type of cancer, CVD and cancer), we created a stacked QCancer model by taking the average of the logit-transformed predicted risks of all applicable cancer types (i.e., including prostate cancer for men and breast, ovarian and uterine cancers for women).The models were

recalibrated (and independently evaluated) to improve an anticipated lack of calibration due to the difference between CVD incidence and that of individual cancers.

Statistical analysis

The models were evaluated in terms of discrimination (c-statistic) and calibration (calibration intercept and calibration slope) including 95% confidence intervals (CIs). A c-statistic of 0.5 indicates the model is not able to discriminate between people who will and will not develop disease, whereas 1 represents perfect discrimination(9). Calibration measures how well the model's predicted risk aligns with observed risk of experiencing the outcome being predicted. A calibration intercept of 0 and slope of 1 indicate perfect calibration(10).

To facilitate recalibration and unbiased evaluation of the prediction models, we first split the UKB cohort into 20% training and 80% testing sets, where the former was exclusively used to recalibrate the CVD and QCancer prediction models, and the testing set used to determine calibration and discrimination. Recalibration consisted of a rank-preserving (i.e., without affecting discrimination) transformation, deriving an outcome specific model update for the intercept and slope.

Permuted feature importance was performed on QRISK3, the most widely used CVD risk score in the UK. Each feature is randomly shuffled (50 times) in turn, with the resulting change in c-statistic representing the feature-specific contribution to model discrimination(16).

Sensitivity and subgroup analyses

Our primary analysis focused on 10-year outcomes to align with the typical time frame used in CVD risk assessment for primary prevention. We additionally explored model performance over 1-, 2- and 5-years of follow up, and carried out a landmark analysis, removing any cancer event occurring within the first 3 years of available follow-up. This was to investigate the effects of removing sub-clinical or early onset cancers that may be less amenable to primary prevention interventions.

In the main analysis, we excluded participants with missing data for any of the predictor or outcome variables. As a sensitivity analysis, we re-ran the models after imputing missing data in the CPRD replication cohort using the *missRanger* package in R(12).

Patient and public involvement and engagement

Patient representatives and members of the public helped to define the scope of outcomes to be included in the study and advised on communication of results to the wider public.

Results:

Data were available from 502,126 UKB and 4,810,089 CRPD participants. The mean age was 56·6 years (standard deviation (SD): 8·1) in UKB and 58·5 (SD: 11·9) in CPRD; 54·4% and 50% were female, respectively. The median follow-up for both UKB and CPRD was 10 years (UKB quartile(Q)1;Q3: 10;10, CPRD Q1;Q3: 6·1;10). Incident CVD developed in 36,766 (7·3%) and 322,250 (6·7%) respectively, incident cancer in 53,821 (10·7%) and 752,554 (15·6%) respectively, and both conditions in 5,710 (1·1%) and 73,243 (1·5%) respectively (Supplemental Tables S2-S3).

Discrimination for incident CVD and cancers

The c-statistics for CVD at 10-years were 0·74 (95%CI 0·73;0·74) for QRISK3, 0·72 (95%CI 0·72;0·73) for PCE and SCORE2, and 0·71 (95%CI 0·71;0·72) for SCORE2-OP. The stacked QCancer model had a c-statistic of 0·65 (95%CI 0·64;0·65) for any cancer. This was higher than the CVD models, which all had a c-statistic of 0·63 (95%CI 0·63;0·64 for QRISK3 and SCORE2-OP, 95%CI 0·62;0·63 for PCE and SCORE2) for any cancer. All four CVD models had c-statistics of 0·70 or higher for the following individual cancers: gastro-oesophageal, liver and biliary tree, laryngeal, renal tract, any lung cancer, and lung cancer in smokers; Figure 1. Aside from the QCancer's markedly higher c-statistic for lung cancer, the discriminative performance was similar between the CVD and QCancer models for all other outcomes (median difference: 0·01 95%CI -0·02;0·00).

The CVD and QCancer models were able to identify people who developed both CVD and cancer (c-statistic range: 0·76 for SCORE2, 0·78 for QRISK3), and discrimination was higher still for cancer diagnoses following a CVD event (Figure 1 and Supplemental Table S4). The c-statistics for the negative control, accidental injury, ranged from 0·55 (95%CI:0·54;0·55) for PCE to 0·56 (0·55;0·57) for QRISK3.

Calibration for incident CVD and cancers

Recalibrating the models markedly improved the agreement between observed and predicted risk (evaluated in the 80% testing data). Overall, the calibration intercepts were close to 0 (median: 0·00, Q1:-0·02, Q3:0·12) and calibration slopes were close to 1 (median 1·04, Q1:1·03, Q3:1·05); Supplemental Table S4. There was no meaningful difference in calibration between the CVD and QCancer models (median difference: 0·02 (95%CI -0·04;0·06) for the intercept; 0·01 (95%CI -0·06;0·08) for the slope); Figure 2, Supplemental Table S4.

External validation in CPRD

Model discrimination was similar across the UKB and CPRD. The median c-statistic for the CVD models was slightly higher in CPRD than to UKB (0.01, 95%CI 0.00;0.02). The c-statistics for all models were highly correlated between the two datasets; Spearman correlation (r) range 0·76 for PCE to 0·86 for QRISK3; Figure 3. Similarly, the difference in calibration between UKB and CPRD was small (median intercept difference: -0·06, 95%CI -0·02;0·17), median slope difference: 0·01 95%CI -0·08;0·06); Figure 3.

Sensitivity analyses

Discrimination did not meaningfully differ across 1-, 2-, 5- and 10-year follow-up periods (Supplemental Figures S1 & S2). Similarly, the landmark analysis excluding cancers diagnoses in the first 3 years of follow-up did not meaningfully affect model performance (Figure 3 and Supplemental Table S5). Comparing the c-statistic results based on the complete-cases set of the CPRD against the c-statistic using the imputed CPRD data showed reasonable agreement (correlation range between 0·78 and 0·87), with a median difference of -0·02 (95%CI -0·03;-0·02) (Supplemental Figure S3 and Table S5).

Feature importance for predicting incident cancer

The permuted feature importance analysis indicated that smoking status was particularly important for nearly all cancers (aside from cancers of the prostate, uterus, ovaries, melanoma and smoking-stratified lung cancer), and specifically any laryngeal cancer and any lung cancer; Figure 4. Systolic blood pressure (SBP), total cholesterol to high-density lipoprotein cholesterol ratio, Townsend Deprivation Index, and family history of CVD showed a similar cross-cancer importance.

Discussion:

We successfully repurposed four widely used CVD prediction models (QRISK3, PCE and SCORE2 and SCORE2-OP) to additionally identify people at risk of developing cancers. The repurposed CVD models had comparable performance to QCancer benchmark models for many common cancer types with established or emerging screening programmes, such as colorectal, breast, and prostate cancer. For lung cancer, the QCancer model had higher discrimination (c-statistic: 0.80 95%CI 0.79;0.81) than the repurposed CVD models overall (best c-statistic: 0.75 95%CI 0.73;0.76) for SCORE2-OP). However, among people with no history of smoking, the QCancer and repurposed CVD models performed similarly (c-statistic: 0.65 95%CI: 0.62;0.68 for both QCancer and SCORE2-OP). The repurposed models had a discriminative performance similar or better to that

of CVD (c-statistic of 0·70 for several for several cancer types without established screening programmes, including renal tract, laryngeal, and gastro-oesophageal cancers, as well as cancers of the liver or biliary tree. The repurposed CVD models were able to identify people who developing both CVD and cancer (best c-statistic 0·78 95%CI 0·77;0·79 for QRISK3).

Although the original repurposed CVD models were generally poorly calibrated, recalibration markedly improved this in both UKB and on external validation in CPRD. In particular, the PCE model reached near-perfect calibration in both cohorts. The feature importance analysis showed that after age, smoking and SBP were the risk factors that contributed most to model performance in both men and women. These are well-established risk factors for many types of cancers, as well as for CVD, which provides a plausible explanation for why the repurposed CVD models also perform well when predicting cancer.

Disease prevention is a top priority for health systems worldwide. One of the core commitments in the UK's *Fit for the Future* 10-Year Health Plan is to shift "from sickness to prevention" through early recognition and management of risk, long before disease develops[13]. Despite overlapping risk factors and similar preventative interventions, primary prevention strategies for CVD and cancer have historically been implemented separately[14]. Recognising the overlap between CVD and cancer risk, *Pursnani et al.* explored whether statin eligibility criteria overlapped with cancer risk[15], *Ogunmoroti et al.* determined the associations between Life's Simple 7 lifestyle score and cancer incidence[16], and *Handy et al.* associated coronary artery calcifications scores with cancer risk[17]. We sought to build on this work by developing formal cancer-specific risk prediction models, evaluating them in large sample size settings, and providing relevant external validation. We deliberately focused on repurposing models and data modalities that are currently available in most GP settings.

By repurposing CVD models already in active clinical use across Europe, the UK, and the US, our proposed approach has potential to challenge the existing cancer prevention paradigm, with limited additional resource demands for implementation. In the UK, the QRISK3 model is built into existing electronic health record systems e.g. in primary care and in the NHS Health Check, a national primary prevention programme for adults aged 40-74[18,19]. This existing infrastructure for CVD risk assessment can readily be expanded to support cancer prevention initiatives, for example, generating prompts based on CVD risk scores that suggest interventions that reduce cancer risk or inviting high-risk individuals to join relevant cancer screening programmes.

Aligning cancer and CVD risk assessment using a single tool could have synergistic effects in preventing both conditions(14). Articulating elevated cancer risk alongside CVD risk would provide additional impetus for clinicians to encourage - and for patients to adopt - healthier lifestyles, alongside statin and antihypertensive therapy. Though medications are not currently used in cancer prevention, newer pharmacological agents, such as glucagon-like peptide-1 receptor agonists, may reduce risks of obesity-related cancers, which could lead to medicines having a more central role in primary prevention of cancer in the future(20,21).

While we sought to repurpose CVD models primarily to identify people at increased risk of developing novel cancers (rather than screen for subclinical disease), we acknowledge that at-risk individuals may require more focused monitoring. A possible avenue of future research might therefore be the effectiveness of prioritised screening in people who are predicted to be at-risk of developing cancer. Both healthcare professionals and the general public are receptive to personalised, risk-based approaches to cancer screening(22). The repurposed CVD models could enable risk-based cancer screening programmes to be rapidly adopted into clinical practice. In the UK, low-dose CT (LDCT) for lung cancer screening is offered to current or ex-smokers aged 55-74. Using our repurposed CVD models for recruitment would instead allow for lung cancer screening thresholds and intervals to be individualised based on predicted risk. Similar opportunities also exist around risk-based screening of both CVD and cancer, particularly given that LDCT may also be relevant for detecting early evidence of coronary artery calcification(23).

For cancers where population screening is not currently recommended due to limited test specificity (such as prostate-specific antigen testing for prostate cancer) or low disease incidence (e.g. renal and gastro-oesophageal cancers), targeting high-risk populations could make screening viable(46–49). Multi-cancer early detection tests, like the Galleri test®, would likely be more affordable if deployed in people with a relatively higher risk to developing cancer, rather than on offering screening based on age alone(24).

There are several additional strengths of this study worth mentioning. Firstly, despite some differences in risk factor distributions and disease occurrence, we found comparably strong performances of the CVD models across both datasets for most outcomes. For example, average SBP was higher in UKB (138 mmHg; SD: 18.7) than in CPRD (132 mmHg; SD: 15.7), and fewer people developed cancer after 10 years of follow-up in UKB (53,821; 10.7%) compared to CPRD (752,554; 15.6%). Nonetheless, the median c-statistic was only 0.01 higher in CPRD compared to UKB (95%CI 0.00;0.02). This indicates the repurposed models are relatively robust to variation across different populations and likely reflects how they would perform in clinical practice.

Secondly, in our landmark analysis, we excluded all events within 3 years of baseline and demonstrated that the CVD models are able to identify cancers that develop *de novo*. This shows the repurposed CVD models can identify high-risk individuals at an early enough time, when risk reduction may prevent the development of cancer.

The following potential limitations require consideration. By restricting our analysis to adults aged 40-84 at study entry, we exclude young-onset cancers and cancers that develop at very advanced ages. However, young onset cancers typically have a distinct aetiology from cancers that develop in mid-to later life and are typically less amenable to primary prevention. Furthermore, some variables (e.g. BMI, cholesterol levels, smoking history) were only partially observed (particularly in the CPRD). However, repeating our analysis after imputing missing data in CPRD did not substantially affect the findings of the study. The limited impact of missing data on our results is also supported by the high degree of agreement between relatively simple models such as the PCE, which used nine predictors, and the more expansive QRISK3 model which requires information on over 20 variables.

Conclusion:

CVD prediction models can be repurposed to identify individuals at risk of cancer, as well as those at risk of both CVD and cancer. These repurposed, clinically used CVD models support deployment of targeted intervention for cancer prevention, as well as risk-based approaches to monitoring and cancer screening.

Availability of data and materials:

The repurposed CVD models have been made available at:

 https://repurposed-cvd-risk-models.shinyapps.io/cvd_cancer_risk_app/

Data are available from the UK Biobank and the Clinical Practice Research Datalink.

Competing interests:

AFS has received funding from NewAmsterdam Pharma for unrelated work. NC receives funds from AstraZeneca pharmaceuticals to serve on Data Safety and Monitoring Committees for clinical trials. The remaining authors confirm they have no competing interests.

Funding:

Table 1. Baseline characteristics of participants in UK Biobank and CPRD cohorts.

Variable	UKB Mean (SD) or N (%)	UKB Missing (%)	CPRD Mean (SD) or N (%)	CPRD Missing (%)
Overall sample size	502,126		4,810,089	
Follow-up time in years (median, Q1/Q3)	10 (10; 10)		10 (6.1; 10)	
Age (years)	56.6 (8.1)	0 (0%)	58.5 (12.1)	0 (0%)
Female sex (UKB), gender (CPRD)	273,158 (54.4%)	0 (0%)	2,404,320 (50%)	24 (<0.1%)
Mean systolic blood pressure (mmHg)	138 (18.7)	1,318 (0.3%)	132 (15.7)	760,049 (15.8%)
Total cholesterol (mmol/L)	5.7 (1.1)	32,874 (6.5%)	5.1 (1.1)	1,744,818 (36.3%)
HDL cholesterol (mmol/L)	1.4 (0.4)	72,567 (14.5%)	1.4 (0.4)	2,037,512 (42.4%)
BMI (kg/m^2)	27.4 (4.8)	3,328 (0.7%)	27.3 (5.6)	1,264,154 (26.3%)
Personal history of:				
Cardiovascular disease	33,768 (6.7%)		601,219 (12.5%)	
Bowel cancer	2,860 (0.6%)		29,903 (0.6%)	
Lung cancer	454 (0.1%)		8,868 (0.2%)	
Breast cancer	11,449 (2.3%)		71,942 (1.5%)	
Prostate cancer	3,570 (0.7%)		43,748 (0.9%)	
Family history of:				
Cardiovascular disease	215,137 (42.8%)	10,746 (2.1%)	1,062,660 (22.1%)	0 (0%)
Bowel cancer	54,590 (10.9%)	91,262 (18.2%)	58,262 (1.2%)	0 (0%)
Lung cancer	62,172 (12.4%)	88,170 (17.6%)	20,942 (0.4%)	0 (0%)
Breast cancer	52,464 (10.4%)	91,759 (18.3%)	79,216 (1.6%)	0 (0%)
Prostate cancer	38,760 (7.7%)	95,388 (19%)	4,174 (0.1%)	0 (0%)
Ethnicity:		895 (0.2%)		247,082 (5.1%)
White or not stated	474,238 (94.4%)		4,149,937 (86.3%)	
Indian	5,944 (1.2%)		88,287 (1.8%)	
Pakistani	1,833 (0.4%)		39,493 (0.8%)	
Bangladeshi	236 (<0.1%)		14,630 (0.3%)	
Other Asian	2,687 (0.5%)		52,242 (1.1%)	
Black Caribbean	4,509 (0.9%)		37,749 (0.8%)	
Black African	3,390 (0.7%)		70,684 (1.5%)	
Chinese	1,573 (0.3%)		18,233 (0.4%)	
Other ethnic group	6,821 (1.4%)		91,752 (1.9%)	
Smoking status:		19,745 (3.9%)		588,137 (12.2%)
Non-smoker	273,336 (54.4%)		2,351,207 (48.9%)	
Ex-smoker	172,923 (34.4%)		1,234,591 (25.7%)	
<10 cigarettes/day	7,207 (1.4%)		200,791 (4.2%)	
10-19 cigarettes/day	15,420 (3.1%)		255,872 (5.3%)	
>19 cigarettes/day	13,495 (2.7%)		179,491 (3.7%)	

Figures

Figure 1. Discrimination of CVD and cancer risk prediction models for incident cancers, incident CVD, composite CVD and cancer outcomes, and accidental injury (negative control).

The red, vertical dashed line represents the performance of QRISK3 for CVD at 10 years (c-statistic of 0·74, 95%CI :0·73; 0·74). The vertical dashed black line indicates the c-statistic value of 0·5. For each outcome people with historic disease (e.g. any cancer or any CVD) were excluded (Supplemental Tables S2/S3). For sex-specific cancers or cancers which are predominant in either males or females (incidence lower than 0·1%), performance was evaluated on the relevant sex-specific subgroup (Supplemental Tables S2-S3) Abbreviations: 95% CI, 95% confidence interval; CPRD, Clinical Practice Research Datalink; CVD, cardiovascular disease; Gynae. Gynaecological; H&N, head and neck; UKB, UK Biobank.

Figure 2. Calibration plots comparing the repurposed CVD risk models to QCancer risk models for different cancer outcomes in UK Biobank data after model recalibration.

Calibration plots comparing predicted risk (x-axis) with observed risk (y-axis) between the four CVD risk models (QRISK3, PCE, SCORE2, SCORE2-OP) and QCancer model for five outcomes; any cancer, colorectal and anal cancer, gastro-oesophageal cancer, renal tract cancer, and the CVD and cancer endpoint. Each point represents a risk decile. Points on the solid diagonal line indicate perfect estimation of risk. Participants with missing predictor or outcome data were excluded from both cohorts. For each outcome, participants with prevalent disease were excluded (Supplemental Tables S2-S3).

Figure 3. A comparison of the discrimination and calibration of each model between the UK Biobank and CPRD datasets, and for the landmark analysis on the UKB.

Correlation between model performance metrics (discrimination, calibration intercept, and calibration slope) comparing UKB to CPRD (top row) and in the full UKB cohort to the landmark analysis excluding cancer diagnoses in the first 3 years of follow-up (bottom row). The correlation (r) was calculated using Spearman's rank correlation test. The diagonal line in the discrimination plots (left column) indicates perfect correlation. The intersection of the dashed lines in the calibration intercept and slope plots (middle and right columns) corresponds to perfect agreement across datasets. The colours of the dots represent to each of the models evaluated (see legend). Participants with missing predictor or outcome data were excluded from both cohorts. For each outcome, those with prevalent disease were also excluded (see Supplemental Tables S2-S3). Δ indicates change between the dataset on the y-axis to the x-axis. For example, the calibration slope for QRISK3 was 0·07 higher in CPRD compared to UKB. Abbreviations: CPRD, Clinical Practice Research Datalink; UKB, UK Biobank.

Figure 4. Feature importance in the QRISK3 model for cancer, cardiovascular disease and composite outcomes.

The feature importance results for the QRISK3 model for each outcome, measured as the change in C-statistic when each variable is randomly permuted. The top panel (blue) shows results for male participants (including male-specific cancers) and the bottom panel (yellow) shows results for female participants (including female-specific cancers). Predictor variables (y-axis) are ordered by overall importance across all outcomes. The darker shading indicates greater importance (larger decrease in discrimination when variable is removed). The white tiles with a small, black horizontal line indicate which features did not contribute to the c-statistic in the QRISK3 model for that outcome. Abbreviations: AF, atrial fibrillation; BMI, body mass index; BP, blood pressure; CKD, chronic kidney disease; CVD, cardiovascular disease; HDL-C, high-density lipoprotein Cholesterol; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus.
