Abstract

Tobacco use disorder (TUD) remains a leading cause of preventable mortality, and existing pharmacotherapies yield 12-month abstinence rates below 30%. As cannabis legalization expands, approximately 18-22% of people who use tobacco report concurrent cannabis use, yet the impact of co-use on cessation outcomes and the therapeutic potential of endocannabinoid system (ECS) modulation remain unclear. We conducted a translational systematic review and meta-analysis following PRISMA 2020 guidelines, searching Ovid MEDLINE, Embase, APA PsycInfo, and Web of Science through January 2026 (PROSPERO: CRD420250652724). Three study categories were eligible: observational studies of cannabis co-use and cessation outcomes; preclinical studies of cannabinoid modulators on nicotine-related behaviors; and human experimental studies of ECS-targeted interventions. Of 4,869 records screened, 52 studies met inclusion criteria. Meta-analysis of 18 observational studies (N=229,630) revealed that cannabis use was associated with 35% lower odds of achieving tobacco cessation (OR=0.65; 95% CI: 0.55-0.78; p<0.0001; I²=88.1%). Preclinical evidence (15 studies) demonstrated that CB1 receptor antagonists robustly reduced nicotine self-administration and reinstatement, while cannabidiol (CBD) attenuated both nicotine intake and withdrawal without affecting food reinforcement. Clinical translation of CB1 receptor inverse agonists failed due to psychiatric adverse effects, but CBD showed promise by reducing cigarette consumption by 40%, reversing attentional bias to smoking cues, and alleviating withdrawal severity. These findings distinguish naturalistic cannabis exposure from potentially beneficial targeted ECS modulation, and support CBD as a promising candidate for adequately powered tobacco cessation trials.

Keywords: tobacco use disorder; cannabis co-use; endocannabinoid system; cannabidiol; CB1 receptor; tobacco cessation

1. Introduction

Tobacco use disorder (TUD) is a leading cause of preventable mortality globally, accounting for more than 7 million deaths annually and imposing a substantial burden through cardiovascular disease, malignancy, and respiratory illness[1,2]. In the U.S., approximately 28.3 million adults currently use tobacco or electronic cigarettes (e-cigarettes), and despite decades of public health efforts, the majority of quit attempts fail; fewer than 10% of smokers achieve long-term abstinence without pharmacological support[3,4]. While FDA-approved pharmacological treatments, including nicotine replacement therapy (NRT), bupropion, and varenicline, increase cessation rates 2- to 3-fold compared to placebo[3,5], many individuals do not benefit from these treatments. This therapeutic ceiling, combined with the limited range of pharmacological mechanisms targeted by available pharmacotherapies, underscores the need to identify novel therapeutic approaches for TUD.

Against the backdrop of limited treatments for TUD, the rapid expansion of cannabis legalization across North America and Europe has introduced the rising prevalence of cannabis-tobacco co-use. National survey data indicate that approximately 18-22% of people who currently use tobacco report concurrent cannabis use[6-8]. Cannabis and tobacco are frequently co-administered within the same product (e.g., blunts, spliffs), a practice that creates pharmacological and behavioral interactions that potentially reinforce the use of both substances[9-11]. Epidemiological evidence suggests that people who co-use tobacco and cannabis, particularly people who use cannabis daily, may exhibit greater nicotine dependence severity, increased frequency of failed quit attempts, and elevated relapse vulnerability, compared to people who use tobacco only. However, this association may not extend to people who use cannabis non-daily[9,11-13]. As cannabis access continues to expand, understanding whether and how co-use impacts tobacco and nicotine product cessation outcomes has become a clinical priority. Throughout this review, "cessation" refers to abstinence from combustible cigarettes, e-cigarettes, or both, as defined by the individual study.

[Figure 1]

1.1. Crosstalk Between Endocannabinoid and Nicotinic Cholinergic Pathways

The extensive crosstalk between the endocannabinoid system (ECS) and the nicotinic cholinergic receptors (nAChR) underscores the therapeutic potential of targeting the ECS for TUD. The endocannabinoid system (ECS) comprises cannabinoid receptors (primarily CB1 and CB2), endogenous ligands including anandamide (AEA) and 2-arachidonoylglycerol (2-AG)[14]. The signaling activity of AEA and 2-AG is terminated primarily by fatty acid amide hydrolase (FAAH) and monoacylglycerol lipase (MAGL), respectively[15]. CB1 receptors (CB1R)[16] are densely expressed throughout the brain reward-related circuitry, including the ventral tegmental area (VTA), nucleus accumbens (NAc), prefrontal cortex, and amygdala, where they serve as retrograde modulators of glutamatergic and GABAergic transmission[17,18].

The nAChR are ligand-gated ion channels that are pentameric assemblies of 12 distinct subunits: α2-α10 and β2-β4[19,20]. In the brain, the most prevalent subtypes are heteromeric α4β2* *(* denotes possible inclusion of additional subunits)* and homomeric α7 nAChR. The activation of nAChR facilitates the release of key neurotransmitters, including dopamine, acetylcholine, GABA, and glutamate. Dopamine release in the NAc, central to the reinforcing effects of nicotine, is mediated primarily by α4β2* nAChR. The NAc also integrates GABAergic and glutamatergic inputs that inhibit and stimulate nicotine-induced DA release, respectively. The nAChR subtypes that regulate GABA release (primarily α4β2*) desensitize more rapidly than those that regulate glutamate release (primarily α7)[21,22]. With chronic nicotine exposure, this relative deficiency of inhibitory GABA compared to excitatory glutamate represents a key mechanism facilitating dopamine release and the development of nicotine dependence.

Convergent evidence supports bidirectional modulation between ECS and nAChR. In rodent models, nicotine self-administration increases the release of AEA and 2AG from post-

synaptic neurons in the NAc[23]. By activating presynaptic CB1R via retrograde signaling, these endocannabinoids reduce the release of both GABA and glutamate within NAc[24]. This reduced GABA release is suggested to amplify dopamine signaling by removing the inhibitory brake[25,26]. Critically, CB1R is essential in mediating the reinforcing effects of nicotine, as CB1R antagonists effectively block these reinforcing effects. Chronic nicotine exposure further alters endocannabinoid signaling[27], with preliminary evidence suggesting that people who co-use cannabis and tobacco have higher FAAH activity and lower AEA levels across multiple brain regions, compared to those who exclusively use either substance[28]. Reduced AEA levels are associated with sleep disturbance, anxiety, and anhedonia, and greater sensitivity to physical discomfort and pain (e.g., hyperalgesia), and may contribute to increased withdrawal severity and lower cessation success among co-users[29,30]. Evidence from positron emission tomography (PET) imaging studies in humans also indicates that chronic nicotine exposure is associated with lower density of CB1R[31], likely reflecting ECS adaptations induced by long-term nicotine use. Collectively, these findings underscore the ECS as a promising target for novel tobacco cessation treatments, particularly among individuals who co-use cannabis and tobacco.

This neurobiological intersection between the ECS and nAChR raises two complementary questions: First, if exogenous cannabinoid exposure engages the same circuitry that modulates nicotine reinforcement, does co-use of tobacco and cannabis alter tobacco cessation outcomes? Second, can pharmacological interventions targeting specific ECS components, distinct from uncontrolled cannabis exposure, provide therapeutic benefit for TUD?

To address these questions, we conducted a translational systematic review and meta-analysis. We quantitatively synthesized observational evidence on cannabis and tobacco co-use and cessation outcomes and systematically evaluated preclinical and human experimental studies of ECS modulators, including CB1R antagonists, endocannabinoid enzyme and transport inhibitors, and CBD, as potential therapeutic targets. In doing so, we sought to (1) quantify the clinical impact of cannabis co-use on cessation success, (2) identify ECS

mechanisms with therapeutic promise, (3) elucidate translational barriers, and (4) clarify the variables determining the distinction between naturalistic cannabinoid exposure and targeted pharmacotherapy.

2. Methods

This systematic review and meta-analysis is reported in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) 2020 guidelines[32]. The protocol was prospectively registered with PROSPERO CRD420250652724.

2.1 Search Strategy

We searched Ovid MEDLINE, Embase, APA PsycInfo, and Web of Science from inception through December 2024, with a final search update conducted in January 2026. The search strategy combined terms related to the ECS (cannabinoid, endocannabinoid, CB1, CB2, anandamide, 2-AG, CBD, tetrahydrocannabinol, rimonabant, FAAH) with nicotine/tobacco-related terms (nicotine, tobacco, smoking, cigarette, cessation, withdrawal). Reference lists of eligible studies and relevant systematic reviews were manually screened. Complete search strategies are provided in **Supplementary eMethods**.

2.2 Eligibility Criteria

Given the review's dual objectives, (1) evaluating whether naturalistic cannabis co-use is associated with tobacco cessation outcomes and (2) assessing whether targeted ECS modulation offers therapeutic potential for TUD, three study categories were eligible.

First, observational studies examining the association between cannabis use (exposure) and tobacco or nicotine product abstinence or relapse among individuals receiving any

cessation intervention. Studies were required to report odds ratios, relative risks, or sufficient data permitting their calculation.

Second, preclinical studies comprising controlled experiments using animal models examining effects of cannabinoid system modulators on nicotine-consumption, including self-administration, reinstatement of nicotine use, and conditioned place preference.

Third, human experimental studies including randomized controlled trials, crossover designs, and laboratory paradigms evaluating cannabinoid interventions for tobacco-related outcomes (consumption, craving, withdrawal, cue reactivity, cessation) or examining mechanistic interactions between cannabis and tobacco.

2.3 Data Extraction and Synthesis

Two reviewers (G.C. and O.G.) independently screened titles/abstracts and full texts, with discrepancies resolved by consensus discussion. Data extraction employed standardized forms tailored to each study category. For observational studies, we extracted odds ratios (or calculated them from reported data), confidence intervals, sample sizes, cannabis use definitions, cessation outcomes, and adjustment variables.

Only the observational studies examining cannabis co-use and tobacco cessation outcomes were considered meta-analyzable, as they reported a common effect measure (odds ratios for cessation) with sufficient methodological homogeneity for quantitative pooling. Quantitative synthesis of preclinical and human experimental studies was precluded by the heterogeneity in species, compounds, dosing regimens, outcome measures, and study designs.

For the meta-analyzable observational studies, we employed inverse-variance random-effects models with restricted maximum likelihood estimation of between-study variance (τ^2). Heterogeneity was assessed using Cochran's Q statistic, τ^2, and I^2. R version 4.5.2 was used for

all analyses. For preclinical and human experimental studies, synthesis was narratively organized by cannabinoid mechanism given heterogeneity in designs and outcomes.

2.4 Risk of Bias Assessment

We assessed risk of bias in randomized trials using the Cochrane Risk of Bias 2 (RoB 2) tool and observational studies using the Risk of Bias in Non-randomized Studies of Interventions (ROBINS-I) tool. No formal quality assessment was conducted for preclinical studies due to lack of widely accepted tools for animal studies.

3. Results

Database searches identified 4,869 records after deduplication. Following title and abstract screening and a full-text review of 216 articles, 52 studies met the inclusion criteria: 18 observational studies examining cannabis as a predictor of cessation, 15 preclinical studies evaluating cannabinoid modulators, and 19 human experimental studies (**Figure 2**).

The results are organized to first examine the impact of co-use on cessation (observational evidence), followed by an exploration of the therapeutic potential of cannabinoid interventions (preclinical and human experimental evidence).

[Figure 2]

3.1 Cannabis Co-Use and Tobacco Cessation: Observational Evidence

Eighteen observational studies contributing 20 independent estimates (total N=229,630) examined whether cannabis use predicted tobacco cessation outcomes among individuals receiving cessation interventions. Follow-up ranged from end-of-treatment to 12 months, with 6-month assessment most common.

Meta-analysis yielded a pooled odds ratio of 0.65 (95% CI: 0.55-0.78; p<0.0001), indicating that people who use cannabis have 35% lower odds of achieving cessation compared to people who do not use cannabis (**Figure 3**). Between-study heterogeneity was high (I²=88.1%; 95% CI: 83.1-91.7%; τ²=0.10; Cochran's Q=160.24, df=19, p<0.0001), reflecting substantial variability in effect magnitude. Visual inspection of the funnel plot did not reveal marked asymmetry (**Supplement Figure S1**) and neither Egger's regression test (p = 0.071) nor Begg's rank correlation test (p = 0.948) indicated significant publication bias.

[Figure 3]

3.2 Endocannabinoid System Modulation of Nicotine-Related Behaviors: Preclinical Evidence

Fifteen preclinical studies examined ECS modulation of nicotine-related behaviors using rodent and primate models across 17 experiments (**Table 1**). Paradigms included intravenous nicotine self-administration under fixed-ratio and progressive-ratio schedules, reinstatement models (cue-induced, nicotine-primed, contextual), conditioned place preference, and withdrawal assessment. Interventions were categorized by mechanism: CB1R antagonists/inverse agonists (n=6), CB1R agonists (n=2), CBD (n=1), and other endocannabinoid modulators (n=6).

3.2.1 Cannabinoid 1 Receptor Antagonists/Inverse Agonists

Six preclinical studies examined compounds that reduce CB1R signaling, including inverse agonists (AM251, rimonabant/SR141716A), which not only block receptor activation but also suppress constitutive CB1R signaling, and the neutral antagonist SLV330, all of which demonstrated uniformly positive effects[33-38]. The AM251 reduced nicotine self-administration in

a dose-dependent manner, with nicotine self-administration showing greater sensitivity to AM251 dose than food self-administration, as indicated by significant reductions at 1 and 3 mg/kg, complete blockade at 10 mg/kg. Food self-administration also trended toward reduction at 1 and 3 mg/kg, though this did not reach significance, with only a partial reduction at the highest dose[34]. In addition to nicotine taking, AM251 also reduced nicotine reinstatement in a dose-dependent manner[34]. Rimonabant decreased nicotine self-administration and additionally blocked nicotine-induced dopamine release in the NAc shell and bed nucleus of the stria terminalis, providing mechanistic support for behavioral observations[33]. Regional specificity studies demonstrated that intra-VTA, but not intra-NAc, AM251 infusions attenuated self-administration, indicating that CB1Rs in the VTA, but not in the NAc, control nicotine self-administration[38].

The neutral antagonist SLV330, which was developed to improve safety profiles by blocking agonist effects without suppressing baseline receptor activity, reduced both nicotine self-administration and cue-induced reinstatement, showing consistency with the above mentioned ligands[36]. CB1R blockade also consistently attenuated reinstatement, including context-induced renewal[35] and priming-induced reinstatement of conditioned place preference[37].

3.2.2 Cannabinoid 1 Receptor Agonists

Two preclinical studies examined CB1R agonists, revealing more complex and context-dependent effects[39,40]. The synthetic CB1/CB2 agonist WIN 55,212-2 produced schedule-dependent effects on nicotine self-administration: decreasing intake under fixed-ratio schedules but significantly increasing breakpoints under progressive-ratio schedules, indicating enhanced motivation for nicotine[40]. However, these effects are likely non-specific, as similar effects were observed on food reinforcement[40]. Although motor impairment was not rigorously assessed (e.g., via rotarod or locomotor activity tests), the parallel reduction in food-reinforced responding at the same doses may suggest that the decrease in nicotine intake under fixed-ratio schedules

likely reflects non-specific behavioral suppression, possibly due to motor impairment at higher doses, rather than a selective effect on nicotine reinforcement.

Δ9-THC produced similarly complex results: 3h post-session administration decreased nicotine intake during acquisition and maintenance, shifted dose-response curves downward, and delayed acquisition of stable self-administration[39]. However, these effects were time-dependent and did not generalize to sucrose reinforcement, suggesting a specific nicotine-cannabinoid interaction rather than non-specific behavioral suppression. The effect of pre-session THC on nicotine intake depended heavily on the daily (post-session) THC dose the rats received throughout the study. Higher pre-session doses (3 and 30 mg/kg) significantly decreased nicotine intake when the rats did not receive any post-session administration. When rats in the moderate daily THC group (3 mg/kg post-session) received a low pre-session dose (0.3 mg/kg), nicotine intake increased, particularly in males, an effect not observed in rats that did not receive daily THC. However, the highest pre-session dose (30 mg/kg) still suppressed their nicotine intake. In addition, rats receiving 30 mg/kg during post-session dose showed a general suppression of responding for nicotine regardless of which pre-session THC dose they were given[39].

3.2.3 Cannabidiol

A single study examined CBD and found that its oral administration dose-dependently decreased intravenous nicotine self-administration in mice at both low (0.03 mg/kg/infusion) and moderate (0.1 mg/kg/infusion) nicotine doses, with significant reductions observed at both 40 and 100 mg/kg CBD without a dose relation[41]. The CBD effects were specific to nicotine reinforcement, with no effect on operant responding for food pellets.

CBD also reduced the severity of some withdrawal symptomology. Following chronic nicotine exposure via osmotic minipump, CBD (30-60 mg/kg) attenuated somatic withdrawal signs and reversed withdrawal-induced hyperalgesia, with a non-significant trend toward

reduced anxiety-like behavior at 60 mg/kg in the light-dark box without affecting locomotor activity.

3.2.4 Indirect Cannabinoid System Modulation and Cannabinoid 2 Receptor Ligands

Six studies examined alternative approaches to cannabinoid system modulation, including fatty acid amide hydrolase (FAAH) inhibitors (2 studies)[42,43], anandamide transport inhibitors (2 studies)[44,45], selective CB2 receptor ligands (1 study)[46], and dual-mechanism compounds (1 study)[47]. These investigations reveal mechanism-specific dissociations between effects on nicotine-taking versus nicotine-seeking behavior.

FAAH inhibitors (URB597, URB694) and anandamide transport inhibitors (AM404, VDM11) consistently attenuated cue-induced and nicotine-primed reinstatement without affecting breakpoints (motivation for nicotine seeking) or ongoing self-administration (nicotine taking) in rats[42,44-46]. In squirrel monkeys, FAAH inhibition shifted nicotine dose-response curves rightward and blocked nicotine-primed reinstatement, effects reversed by the PPAR-α antagonist MK886, implicating non-cannabinoid fatty acid ethanolamides rather than anandamide-mediated CB1R activation[43].

Selective CB2 receptor modulation produced null effects: neither the agonist AM1241 nor antagonist AM630 affected nicotine self-administration or reinstatement[46].

Δ8-tetrahydrocannabivarin, which combines CB1R antagonist and CB2R agonist properties, demonstrated comprehensive efficacy, attenuating self-administration, cue- and nicotine-primed reinstatement, conditioned place preference acquisition, and all three withdrawal measures (anxiety-like behavior, somatic signs, hyperalgesia) without producing conditioned place preference or aversion and without affecting locomotor activity[47].

In summary, CB1R antagonism and indirect endocannabinoid tone modulation consistently reduced nicotine reinforcement and relapse across paradigms, while CB1R agonism produced complex, context-dependent effects. CBD reduced both self-administration

and withdrawal signs without affecting food reinforcement, and CB2R-selective compounds were ineffective.

3.3 Endocannabinoid System Modulation of Nicotine-Related Behaviors: Clinical Evidence

Nineteen human studies examined endocannabinoid system modulation for nicotine addiction, comprising a pooled analysis and individual trials of CB1R inverse agonists (rimonabant, surinabant, taranabant) and six studies of CBD. These investigations employed diverse methodological approaches including randomized controlled trials (parallel-group and crossover), and open-label studies (**Table 2**).

3.3.1 Cannabinoid 1 Receptor Inverse Agonists

Three CB1R inverse agonists (rimonabant, surinabant, and taranabant) underwent clinical evaluation for tobacco cessation. A pooled analysis of three rimonabant trials[48] (STRATUS EU, US, META; N=2,097) found that, at 8-week end-of-treatment, rimonabant 20 mg demonstrated significantly higher prolonged abstinence versus placebo: 21.6% versus 14.7% (OR = 1.61; 95% CI: 1.24, 2.08; p = 0.0004). This advantage persisted at 48-week follow-up: 14.8% versus 10.4% (OR = 1.50; 95% CI: 1.03, 2.17; p = 0.04). The 5 mg dose showed no superiority (OR = 1.05; p = 0.81). The adverse event profile revealed clinically significant concerns: overall events occurred in 69.6% versus 61.0% of placebo recipients, driven by gastrointestinal symptoms and psychiatric manifestations (anxiety: 9.8% vs. 5.7%). Treatment discontinuation rates doubled with rimonabant (11.0% vs. 5.6%; p < 0.001), and post-marketing surveillance ultimately identified serious psychiatric risks including depression and suicidality, leading to market withdrawal in 2008.

A randomized-controlled trial evaluated surinabant (2.5-10 mg/day) in 810 participants over 8 weeks[49]. Four-week continuous abstinence rates showed no dose-response: 22.6%,

22.1%, 21.5% for 2.5, 5, 10 mg versus 25.2% placebo (p trend = 0.40). Surinabant produced dose-dependent weight suppression (0.24-0.75 kg vs. 1.19 kg placebo; p < 0.001). Adverse events reported more frequently with surinabant than placebo included headache (12.9–18.0%), nausea (6.9–14.1%), insomnia (9.4–13.1%), and anxiety (7.9–9.8%), although overall psychiatric disorder rates did not differ meaningfully from placebo (36.2–40.0% vs. 37.8%) and there was no signal for suicidality. Similarly, taranabant (2-8 mg/day titration; N=317) failed to achieve efficacy[50], with continuous abstinence rates of 7.5% versus 6.3% placebo (OR = 1.2; p = 0.678) despite producing significant weight loss and reduced cigarette consumption among non-abstainers. Taranabant was associated with significantly elevated psychiatric adverse events (43.4% vs. 26.6%; p = 0.002), including depression (8.2% vs. 2.5%; p = 0.043), irritability (17.6% vs. 5.7%; p = 0.001), and affect lability (5.0% vs. 0%; p = 0.007). Five participants in the taranabant group endorsed suicidal ideation on the PHQ-9 versus none receiving placebo, though no suicidal behavior was reported.

3.3.2 Cannabidiol

Four studies evaluated CBD for TUD using diverse methodologies. A double-blind, placebo-controlled crossover trial in 24 daily tobacco smokers (≥10 cigarettes/day) examined CBD inhaler (400 µg/actuation) versus placebo for one week with ad libitum use[51]. The CBD group demonstrated ~40% reduction in cigarette consumption (p = 0.002), maintained at 2-week follow-up (p = 0.034). Smoking craving assessed by the Tiffany Craving Questionnaire did not differ between groups.

A subsequent crossover study examined single-dose oral CBD 800 mg effects in 30 overnight-abstinent smokers across multiple cognitive and motivational domains[52]. Attentional bias assessment, using a visual probe task, revealed that placebo-treated and recently abstinent tobacco smokers showed marked bias toward cigarette cues at 200 ms exposure, compared to a satiated state (p = 0.001; d = 0.789). CBD administration produced a comparable

effect, such that attentional bias did not differ from the satiated state (p = 0.82) and was smaller

than that of placebo (p = 0.007). CBD also reduced explicit pleasantness ratings of cigarette

images (p = 0.011; d = 0.514), but did not affect self-reported craving or withdrawal symptoms.

Cognitive performance assessments revealed null effects on delay discounting (p = 0.801),

prose recall (p = 0.244), and n-back tasks (p = 0.472).

Most recently, an open-label crossover study evaluated CBD 320 mg for e-cigarette

cessation in 20 individuals who use tobacco daily experiencing anxiety during withdrawal[53].

Following 4-hour supervised abstinence, CBD significantly reduced withdrawal severity (MTWS-

R: 6.5 vs. 12.0; $p < 0.001$; $d = 0.704$) and state anxiety (STAI-S: 37.0 vs. 48.0; $p < 0.001$;

d=0.514), with large effect sizes. Effects remained significant after controlling for expectancies.

CBD was well-tolerated with mild adverse events (somnolence, nausea, headache) in 4

participants.

3.3.3 Human Experimental Evidence on Tobacco-Cannabis Interactions

Beyond targeted pharmacotherapy, a separate body of human experimental research

has examined how naturalistic, whole-plant cannabis and tobacco co-use interact, providing

mechanistic context for the observational findings in Section 3.1. We organized this literature

into three domains: acute behavioral interactions, cognitive and affective mechanisms, and

clinical implications for withdrawal and relapse.

3.3.3.1 Acute Behavioral and Subjective Effects

Human experimental research examining whether cannabis use acutely alters tobacco

smoking behavior ("chasing") has produced mixed results. A residential study found that active

cannabis smoking significantly decreased the number of daily tobacco smoking bouts but

increased the intensity of smoking within bouts (decreased inter-puff intervals)[54]. However,

subsequent laboratory studies have generally not supported a strong pharmacological drive for

this behavior. Various doses of active cannabis produced no reliable changes in the number of tobacco cigarettes smoked or smoking topography compared to placebo[55]. Similarly, a study on daily people who co-use both substances found that smoking active cannabis did not significantly alter tobacco cigarette craving or puff topography (e.g., puff volume, velocity) compared to placebo, suggesting that the "chasing" phenomenon may be driven more by learning or environmental cues than direct pharmacological interaction[56].

Regarding subjective and physiological effects, nicotine appears to enhance certain responses to cannabis. Pretreatment with a 21-mg transdermal nicotine patch significantly enhanced cannabis-induced increases in heart rate and subjective ratings of stimulation, particularly in male participants[57]. Conversely, regarding the potential for acute cannabis intoxication to act as a "gateway" via motivational changes, a study found that while cannabis intoxication reduced motivation for cannabis (satiation), it did not increase implicit or explicit motivation for tobacco[58].

3.3.3.2 Clinical Tobacco Use Disorder Outcomes

A within-subject study compared withdrawal from cannabis, tobacco, and both substances simultaneously. Simultaneous withdrawal produced more severe anger and aggression than withdrawal from either substance alone, while the overall magnitude of cannabis-only withdrawal was comparable to tobacco-only withdrawal[59].

Two human laboratory studies examined bidirectional relapse dynamics between cannabis and tobacco. People who smoked cannabis daily and also used tobacco cigarettes were more likely to relapse to cannabis use during a laboratory abstinence phase than those who did not smoke cigarettes [60]. Acute tobacco abstinence did not alter cannabis relapse rates compared to smoking as usual [60]. Consistent with this asymmetry, a combined laboratory/inpatient study of 46 individuals who co-use nicotine and cannabis found that varenicline increased tobacco abstinence rates (46% vs. 24%; p = .001), while nabilone, a

synthetic cannabinoid agonist, attenuated cannabis withdrawal symptoms (e.g., irritability; p < .05) but did not reduce cannabis relapse [61].

A secondary analysis of a multi-site, double-blind, laboratory study found that cannabis use status did not moderate the effects of reduced nicotine content cigarettes (RNCC); people who use cannabis and those who do not responded similarly to RNCCs in terms of reduced reinforcement and withdrawal suppression, suggesting that policy-level interventions reducing nicotine content may be equitable across cannabis-using and non-using populations[62].

In summary, acute co-administration does not consistently show to potentiate nicotine reinforcement, but simultaneous withdrawal from both substances appears to amplify negative affect, and tobacco smoking status predicts cannabis relapse. Reduced nicotine content cigarettes appear equally effective regardless of cannabis use status.

4. Discussion

In this translational systematic review and meta-analysis, we synthesized and integrated observational, preclinical, and human experimental evidence to clarify the relationship between cannabinoid signaling and nicotine dependence. Four principal findings emerged. First, observational studies indicate that cannabis co-use is associated with a 35% reduction in the odds of tobacco cessation. Second, preclinical data suggested efficacy signals for certain CB1R inverse agonists; however, clinical translation has thus far been unsuccessful. Although rimonabant demonstrated tobacco cessation efficacy, it was withdrawn due to anxiety, depression, and suicidality, while taranabant and surinabant failed to show cessation benefit, with taranabant additionally linked to depression, irritability, and affective lability. Third, CBD emerges as a promising alternative, given its favorable safety and mechanistic profile. Fourth, human laboratory studies of cannabis–tobacco co-use reveal bidirectional effects on withdrawal

and reinforcement, offering a plausible explanation for the association between cannabis co-use and lower tobacco cessation rates.

4.1. Implications to Understand Tobacco and Cannabis Co-Use Patterns and Cessation

The 35% reduction in cessation odds among individuals receiving tobacco cessation intervention who co-use cannabis (OR=0.65; 95% CI: 0.55-0.78) represents a clinically meaningful effect, particularly given rising co-use prevalence in the context of expanding cannabis legalization. Notably, the magnitude of this association exceeds that of several established negative prognostic factors in large cessation trials, including anxiety disorder (OR=0.71), psychotic disorder (OR=0.73), and prior failed pharmacotherapy attempts (OR=0.78)[63], thereby supporting routine assessment of cannabis use status alongside these risk markers in cessation treatment planning.

At the population level, cannabis-tobacco co-use has increased steadily, rising from approximately 4.4% to 6.2% between 2002 and 2019, and has remained elevated through 2023[64,65]. If the association identified here remains stable as co-use prevalence increases, the population-attributable impact on tobacco control may grow correspondingly, particularly given that people who co-use often present with greater dependence severity and more failed quit attempts at baseline[12,13].

Methodologically, this pooled observational association should be interpreted as robust, but not causal. Observational designs cannot fully adjudicate directionality (e.g., whether cannabis use directly impairs cessation versus marking a higher-risk phenotype), and residual confounding likely contributes. Indeed, people who co-use cannabis and tobacco tend to be younger and male, and present with higher rates of psychiatric comorbidity and polysubstance use[6,11,12], a clinical profile associated with poorer cessation outcomes[6]. As detailed in **Supplementary Table S2**, while most included studies adjusted for key demographic variables and nicotine dependence severity, few accounted for impulsivity or externalizing

psychopathology, and none stratified by cannabis use frequency or quantity. The observed 35% reduction in cessation odds may, therefore, partly reflect a shared vulnerability phenotype rather than a direct pharmacological effect of cannabis on cessation. Still, the consistency of associations across extensively adjusted studies suggests confounding does not fully explain the signal.

Mechanistically, several pathways plausibly link co-use to cessation difficulty, though direct pharmacological effects of Δ9-THC on nicotine reinforcement remain inconclusive (one preclinical study reported enhancement[66]; another found reduction[39]; human laboratory studies have generally not confirmed potentiation). More consistently supported mechanisms include withdrawal amplification, dual abstinence from cannabis and tobacco may intensify negative affect[59], and nicotine dependence may heighten cannabis withdrawal severity[67], and conditioned co-administration, where concurrent use of cannabis/tobacco within the same product creates associative cues that trigger relapse to either drug[10].

Clinically, these findings support routine cannabis use assessment in tobacco treatment settings and treatment plans that anticipate bidirectional craving and withdrawal dynamics.

4.2 Emerging Endocannabinoid Targets for Tobacco Cessation

While preclinical evidence robustly supports CB1R antagonism, with all six studies reporting favorable effects with regional specificity and mechanistic confirmation, clinical translation has failed. Despite demonstrating biological activity taranabant and surinabant showed no cessation efficacy. Taranabant was associated with significantly elevated psychiatric adverse events, including depression and irritability, while surinabant's psychiatric adverse event rates did not differ meaningfully from placebo, though individual symptoms such as insomnia and anxiety were numerically more frequent at higher doses[49,50]. These outcomes may be specific to inverse agonism rather than competitive antagonism, suggesting that CB1R target remains valid but the pharmacological approach requires refinement. For instance, through

neutral antagonists. As a result, the field has shifted toward ECS modulation strategies that bypass direct CB1R blockade.

CBD emerges as the most clinically viable treatment approach targeting the ECS for TUD. Preliminary proof-of-concept[51] is provided by Morgan and colleagues, who observed 40% reduction in cigarette consumption , though this requires replication in adequately powered, rigorously controlled trials. Unlike direct CB1R inverse agonists, CBD engages multiple addiction-relevant pathways[68]: negative allosteric modulation of CB1R may attenuate reward signaling without suppressing constitutive receptor activity[69], thereby avoiding the depressive liability of inverse agonism; 5-HT1A agonism may underlie the anxiolytic and anti-craving effects observed during acute withdrawal[53,70]; TRPV1 activation contributes to modulation of mesolimbic dopamine transmission[71,72]; and FAAH inhibition enhances endocannabinoid tone, which has independently demonstrated anti-reinstatement efficacy in preclinical nicotine models[42,43,73]. Additionally, CBD inhibits nicotine metabolism via CYP2A6[74], potentially prolonging nicotine exposure per cigarette and reducing compensatory smoking, a pharmacokinetic mechanism distinct from its receptor-level effects.

Beyond CBD, minor cannabinoids represent additional emerging targets. Δ8-tetrahydrocannabivarin (Δ8-THCV), which combines CB1R antagonist and CB2R agonist properties, reduced nicotine self-administration preclinically without the psychiatric adverse effect profile of CB1R inverse agonists[47]. FAAH inhibitors and anandamide transport inhibitors similarly attenuated reinstatement-like behaviors in preclinical models[42,44], pointing toward AEA enhancement as a viable mechanistic strategy. Collectively, these emerging targets share a common principle: indirect or partial modulation of the ECS may achieve therapeutic benefit without the liabilities of direct, full CB1R blockade.

Methodologically, advancing CBD (and related ECS tone-modulating approaches) will require careful attention to product characterization (composition/contaminants), dose selection anchored in exposure-response, and endpoint selection that aligns with mechanism (e.g., cue

reactivity, reinforcement, withdrawal coupling), ideally alongside biochemical verification of tobacco and cannabis use.

4.3 Limitations

Several limitations warrant consideration. First, the meta-analysis revealed high heterogeneity ($I^2 = 88.1\%$) across studies, likely reflecting differences in cannabis use definitions, cessation outcome measures, follow-up durations, and abstinence verification methods. Furthermore, this heterogeneity captures the clinical diversity of the included studies (**Supplementary Table S2**), which used different interventions (ranging from pharmacotherapy to digital health tools), targeted distinct populations (e.g., adolescents, adults with diabetes), and included varied nicotine products (combustible cigarettes vs. e-cigarettes). Second, although formal publication bias tests (Egger's $p = 0.071$; Begg's $p = 0.948$) were statistically non-significant, selective reporting of positive findings cannot be excluded. Third, observational designs preclude causal inference, as unmeasured confounders, including psychiatric comorbidity, polysubstance use, and nicotine dependence severity, may partially account for the observed association. Fourth, most included studies did not biochemically verify cannabis use or smoking abstinence, introducing potential misclassification bias. Fifth, nearly all observational studies assessed cannabis use as a binary variable (past 30-day any use vs. none), with route of administration unreported in most cases. This precludes dose-response analysis and limits the distinction of pharmacological effects of cannabis use from shared vulnerability.

Additional limitations should be considered when interpreting the preclinical literature. Female subjects were often not included, and age was not reported, limiting conclusions regarding sex differences and developmental stage (adolescent versus adult). In addition, some studies lacked appropriate controls, such as alternative reinforcers (e.g., food) or positive control compounds, making it difficult to determine whether effects were specific to nicotine.

Finally, many studies did not directly assess potential motor impairments at higher doses and instead relied on speculation to explain non-specific behavioral effects.

4.4 Future Directions

A central translational paradox emerges from this review: naturalistic cannabis co-use is associated with 35% lower cessation odds, yet targeted ECS modulation, particularly CBD, shows therapeutic promise. Three variables likely account for this divergence: (1) ligand composition, as naturalistic cannabis delivers Δ9-THC alongside other phytocannabinoids with widely varying potency and Δ9-THC-to-CBD ratios[66], whereas CBD engages multiple receptor systems without Δ9-THC's bidirectional effects on nicotine reinforcement[39,66]; (2) pharmacokinetics, as smoked cannabis produces rapid Δ9-THC peaks that may promote conditioned co-administration with tobacco[10], whereas oral formulations yield slower, sustained exposure better suited to therapeutic contexts[51,53]; and (3) neuroadaptation state, as simultaneous withdrawal amplifies negative affect beyond either substance alone[59], compounding cessation difficulty among people who co-use who already present with greater dependence severity[12,13]. These hypothesized sources of divergence inform three synergistic research priorities.

First, elucidating the mechanisms by which co-use impairs cessation across addiction stages. The observational association (OR = 0.65) likely reflects contributions from reinforcement, withdrawal, and relapse, but the relative importance of each remains unclear. Human laboratory studies should isolate whether co-use primarily amplifies withdrawal severity, enhances cue-conditioned relapse, or alters reinforcement processing, ideally using paradigms that distinguish these stages within the same individuals. Prospective observational studies with granular cannabis exposure characterization (frequency, quantity, product type, Δ9-THC-to-CBD ratio, route of administration) are needed to move beyond the binary measures that currently preclude dose-response analysis. This is a critical gap because concentration of the

association among people who use cannabis heavily would help distinguish cannabis-specific mechanisms from shared vulnerability.

Second, systematic evaluation of emerging ECS targets. Adequately powered randomized controlled trials of CBD for tobacco cessation, examining dose-response relationships, optimal formulations (inhaled vs. oral), and treatment duration, represent a high priority. Δ8-THCV[47] and FAAH inhibitors[42,43] also merit continued development given consistent preclinical efficacy and mechanistic distinctiveness from failed inverse agonists. The conflicting preclinical findings on Δ9-THC and nicotine reinforcement need resolution through parametric designs systematically varying dose, timing, and chronicity of prior cannabinoid exposure. Additionally, prospective studies should examine whether cannabis co-use moderates response to existing cessation pharmacotherapies (varenicline, NRT); if people who co-use respond differently, tailored treatment algorithms may be warranted.

Third, developing clinical guidance for managing tobacco cessation in people with co-use. This represents the most immediate translational gap: the current evidence establishes that co-use predicts poorer outcomes but provides no management guidance. Key unanswered questions include whether co-use should prompt concurrent treatment of both substances versus sequential approaches; whether routine screening for cannabis use, with attention to frequency, route, and product type, should be incorporated into standard cessation assessments alongside established risk markers such as psychiatric comorbidity and prior failed attempts[63]; and how clinicians should counsel people who co-use regarding the distinction between Δ9-THC-dominant products and ECS-targeted pharmacotherapies under clinical investigation. Integrated behavioral interventions addressing bidirectional withdrawal dynamics and conditioned co-administration may also warrant development.

5. Conclusions

In this translational systematic review and meta-analysis, we have highlighted the endocannabinoid-nicotinic interface as both a clinical challenge and therapeutic frontier.

We provide evidence that cannabis co-use is associated with 35% lower odds of tobacco cessation success. The mechanistic basis of this association remains incompletely understood and may partly reflect confounding by shared vulnerability factors, rather than direct pharmacological effects. These findings, nonetheless, underscore the need for routine co-use assessment in cessation settings. Simultaneously, convergent preclinical studies show that targeted pharmacological modulation of the ECS shows mechanistic promise, particularly through CBD and minor cannabinoids (e.g., Δ8-THCV) that avoid the rapid reinforcement dynamics of smoked, Δ9-THC-dominant products, and the psychiatric adverse effects of CB1R inverse agonists. Finally, building on the evidence synthesized and appraised, we articulate how distinction between naturalistic cannabinoid exposure and targeted pharmacotherapy, determined by ligand composition, pharmacokinetics, and prior neuroadaptations, has direct implications for both clinical practice and therapeutic development.

Table 1. Preclinical studies investigating the effects of CB1R antagonists, inverse agonists, CB1R agonists, endocannabinoid modulators, and other cannabinoid compounds on nicotine use behaviors.

Study	Objective	Species/Strain	Compound (Dose and administration route)	Methods used to investigate nicotine use behaviors	Effect	Key Findings
CB1R Antagonists/Inverse Agonists						
Shoaib 2008[34]	To evaluate the effects of the CB1 inverse agonist AM251 on nicotine taking and reinstatement behaviors in an operant self-administration paradigm	Male hooded Lister rats (initially weighing 200–250 g)	AM251 (1-10 mg/kg, intraperitoneally)	IVSA ; Nicotine: 0.03 mg/kg/infusion	**Positive**	Dose-dependent suppression of nicotine self-administration. Dose-dependent attenuation of reinstatement induced by the combination of nicotine priming and cues. At 10 mg/kg, full blockade of taking and reinstatement behaviors. AM251 also reduced food self-administration; however, nicotine self-administrating rats were more sensitive to AM251 dose, as indicated by full blockade of nicotine self-administration at 10 mg/kg and only a partial reduction in food self-administration
de Bruin 2011[36]	To investigate whether the CB1 inverse agonist SLV330 could reduce and nicotine self-administration and cue-induced reinstatement of nicotine	Male Wistar rats (initially weighing 280–300 g) (young adult)	SLV330 (1-10 mg/kg per os)	IVSA; Nicotine: 0.04 mg/kg/infusion	**Positive**	Reduced nicotine self-administration and cue-induced reinstatement of nicotine only at 10 mg/kg.
Diergaarde 2008[35]	To determine whether context re-exposure reinstates	Male Wistar rats (initially weighing 280–320 g)	SR141716A (Rimonabant) (1-3 mg/kg, intraperitoneally)	IVSA ; Nicotine: 0.03 mg/kg/infusion	**Positive**	Re-exposure to the self-administration, but not extinction,

	nicotine seeking (renewal) and if SR141716A attenuates this effect.				Positive	context reinstated responding for discrete nicotine cues, and this effect decreased with increasing doses of SR141716A
Simonnet 2013[38]	To determine whether cite-specific injections of the CB1 receptor inverse agonist AM251 into the VTA or NAc alter nicotine IVSA	Male Sprague Dawley adolescent rats initially weighing 175–200 g	AM251 (1-10 μg/0.5 μl/side)	IVSA ; Nicotine: 0.03 mg/kg/infusion	Positive	Intra-VTA infusions dose-relatedly reduced nicotine self-administration, with significant decreases at 10 μg. Intra-NAc infusions had no effect on nicotine intake.
Cohen 2002[33]	To evaluate the effects of SR141716 on nicotine taking and discrimination in operant self-administration paradigms, and on nicotine-induced dopamine-release	Male Wistar rats (initially weighing 180–200 g) (adolescent) for drug discrimination studies; male Sprague-Dawley rats (initially weighing 200–220 g) (adolescent) for self-administration and microdialysis studies (initially weighing 280–320 g (late adolescent/young adult))	SR141716A (Rimonabant) (0.03-1 mg/kg, intraperitoneally)	IVSA; Drug discrimination; Microdialysis; Nicotine: 0.03 mg/kg/infusion; Nicotine: 0.4 mg/kg, i.p.; Nicotine: 0.4 mg/kg, s.c.	Positive	Decreased nicotine self-administration (at ≥ 0.1 mg/kg) and antagonized substitution of nicotine for D-amphetamine in a dose-dependent manner. Blocked nicotine-induced dopamine release in the NAc shell in a dose-related manner
Budzyńska 2009[37]	To evaluate the role of CB1 receptors in the reinstatement of nicotine-induced conditioned place preference.	Male Wistar rats (initially weighing 250–300 g)	AM 251 (0.25-0.5 mg/kg, intraperitoneally)	CPP ; Nicotine: 0.5 mg/kg, i.p.	Positive	Attenuated in a dose fashion manner the reinstatement of nicotine-induced CPP triggered by a priming dose of nicotine. Significant effect at 0.5 mg/kg, but not 0.25 mg/kg.
CB1R Agonists						
Gamaleddin 2012a[40]	To investigate the effects of the CB1/2 agonist WIN 55,212-2 on nicotine self-administration behaviors, including taking, seeking, and reinstatement, as well as on	Male Long Evans rats (initially weighing 250–275 g)	WIN 55,212-2 (0.1-1 mg/kg, intraperitoneally)	IVSA; Drug discrimination ; Nicotine: 0.03 mg/kg/infusion; Nicotine: 0.4 mg/kg, i.p.	Mixed	At the highest dose, decreased nicotine intake on FR schedule but increased motivation for nicotine seeking on PR schedule. These effects are likely non-specific as seen similar effects on food

	nicotine discrimination				reinforcement. Increased nicotine reinstatement and potentiated cue-induced reinstatement through a CB1R mechanism. WIN 55,212-2 did not substitute for nicotine but enhanced its discriminative stimulus effects at low doses through CB1 receptor mechanism. Some effects were reversed by rimonabant but not by AM630, confirming a CB1R-mediated mechanism.
Abraham 2023[39]	To examine the effects of co-administration of nicotine and Δ9-THC (experimenter-administered) on acquisition and maintenance of nicotine SA.	Adult Male and Female Sprague-Dawley rats (weight not reported)	Δ9-THC (3, 30 mg/kg for chronic administrations and 0.3-30 mg/kg for acute administrations, intraperitoneally)	IVSA ; Nicotine: 0.001-0.03 mg/kg/infusion	**Mixed**	Chronic post-session Δ9-THC decreased acquisition and maintenance of nicotine self-administration in both sexes. Pre-session THC also decreased intake at 30 mg/kg. Higher pre-session doses (3 and 30 mg/kg) significantly decreased nicotine intake in the absence of post-session THC. However, a simultaneous acute pre-session low-dose Δ9-THC (0.3 mg/kg) increased nicotine intake in males which received 3 mg/kg THC post-session.
Endocannabinoid Modulators (Transport/Enzyme Inhibitors)						

Gamaleddin 2011[44]	To investigate the effects of selective anandamide transport inhibitor VDM11 on nicotine self-administration (taking and seeking) and reinstatement.	Male Long Evans rats (initially weighing 250–275 g)	VDM11 (1-10 mg/kg, intraperitoneally)	IVSA; Nicotine: 0.03 mg/kg/infusion	**Mixed**	Dose-dependently attenuated reinstatement induced by cues and nicotine priming. Did not affect nicotine-taking and motivation for seeking behaviors (FR and PR).
Gamaleddin 2013[45]	To assess the effects of anandamide transport inhibitor AM404 on nicotine taking, seeking, and reinstatement behaviors	Male Long Evans rats (initially weighing 250–275 g)	AM404 (1-10 mg/kg, intraperitoneally)	IVSA ; Nicotine: 0.03 mg/kg/infusion	**Mixed**	Dose-dependently attenuated reinstatement induced by cues and nicotine priming. Did not affect nicotine-taking and motivation for seeking behavior (FR and PR) or food taking behaviors.
Justinova 2015[43]	To investigate the effects of first (URB597) and second (URB694) generation FAAH inhibitors on nicotine reward and relapse	Male Squirrel Monkeys (weighing 0.9–1.1 kg) and Sprague Dawley rats (initially weighing 300–350 g (adult))	FAAH inhibitors (URB597, URB694) (0.1-1 mg/kg IV)	IVSA, Drug discrimination, microdialysis ; Nicotine: 0.003-0.1 mg/kg/injection	**Positive**	Both FAAH inhibitors rightward shifted nicotine dose-response curves (decreased intake at moderate doses but increased at very high nicotine doses) and blocked reinstatement induced by priming or cues. The effects were selective for nicotine. Effects were reversed by PPAR-α antagonist MK886. The blockade of priming-induced relapse was reversed by PPAR-α antagonist but cue-induced relapse was minimal. URB694 was self-administered at moderate rates, unlike URB597.

					In rats, URB694 did not produce THC-like or nicotine-like effects, nor did it enhance the effects of those drugs. Neither FAAH inhibitor increased dopamine release in the nucleus accumbens. Drug discrimination revealed URB694 did not interfere with or mimic THC or nicotine
Forget 2009[42]	To explore the effect of inhibiting FAAH enzyme by URB597 on nicotine self-administration (PR) and reinstatement, compared with Rimonabant.	Male Long-Evans rats (initially weighing 250–275 g)	URB597 (FAAH inhibitor) (0.3-1 mg/kg, intraperitoneally)	IVSA; Nicotine: 0.03 mg/kg/infusion	**Mixed**	Reduced nicotine reinstatement induced by cues or priming. However, unlike Rimonabant, URB597 did not reduce motivation for nicotine seeking (PR).
Other Cannabinoid Compounds / Dual Action					
Xi 2019[47]	To determine whether Δ8-THCV inhibits nicotine self-administration, reinstatement, nicotine reward (CPP), and nicotine withdrawal	Adult male P rats and adult male ICR mice	Δ8-THCV (3-20 mg/kg, intraperitoneally for IVSA and 0.03-30 mg/kg, subcutaneously for CPP)	IVSA: Nicotine: 0.03 mg/kg/infusion; CPP: Nicotine: 0.5 mg/kg, s.c.; Minipump nicotine delivery for withdrawal: Nicotine: 24 mg/kg/day, s.c.	**Positive**	Significantly reduced nicotine self-administration, cue-induced and nicotine-primed reinstatement. Attenuated nicotine-induced CPP irrespective of dose. Attenuated physical signs and anxiety-like behaviors, and hyperalgesia of withdrawal.
Gamaleddin 2012b[46]	To investigate the effects of selective CB2 receptor modulation on nicotine self-administration and reinstatement.	Male Long Evans rats (initially weighing 250–275 g)	AM1241 (CB2 agonist) (1-10 mg/kg, intraperitoneally); AM630 (antagonist), (1.25-5 mg/kg, intraperitoneally)	IVSA; Nicotine: 0.03 mg/kg/infusion	**Neutral**	Neither the selective CB2 agonist (AM1241) nor the selective CB2 antagonist (AM630) affected nicotine self-administration (FR or PR) or reinstatement induced by cues or priming. Suggests CB2

					receptors may not be involved in these specific nicotine behaviors.
Cheeks 2024[41]	To examine whether orally administered CBD would alter nicotine self-administration and withdrawal symptomology.	Adult male and female C57BL/6J mice	Cannabidiol (CBD) (40-100 mg/kg, per os)	IVSA; Minipump nicotine delivery for withdrawal studies; Nicotine: 0.03-0.1 mg/kg/infusion	**Positive** — Acute oral CBD decreased nicotine intake at both low and moderate nicotine doses. Attenuated somatic signs of withdrawal, with a trend toward reversal of nicotine withdrawal-induced anxiety-like behavior at 60 mg/kg. Also prevented withdrawal-induced hyperalgesia. Had no effect on food self-administration, indicating effects are specific to nicotine.

Acronyms: CB1R: cannabinoid type 1 receptor; CB2: cannabinoid type 2 receptor; CBD: cannabidiol; CPP: conditioned place preference; FAAH: fatty acid amide hydrolase; FR: fixed ratio; i.p.: intraperitoneal; IVSA: intravenous self-administration; NAc: nucleus accumbens; PPAR-α: peroxisome proliferator-activated receptor alpha; PR: progressive ratio; s.c.: subcutaneous; SA: self-administration; VTA: ventral tegmental area; Δ8-THCV:*Δ8-Tetrahydrocannabivarin;* Δ9-THC: Δ9-tetrahydrocannabinol

Table 2. Clinical studies investigating the effects of CB1R inverse agonists, cannabidiol, and acute cannabis-tobacco interactions on tobacco-related outcomes.

Study	Study Design	Sample	Intervention	Performance/Behavioral Effects	Subjective Effects	Overall Effect on Tobacco-Related Behaviors
Cannabidiol (CBD) Interventions						
Morgan 2013[51]	Pilot RCT; double-blind; ad libitum use (1 week)	24 individuals who smoke cigarettes wishing to quit (>10 cigs/day)	CBD inhaler (400μg/dose) vs. Placebo; ad-libitum use	Consumption: CBD group reduced cigarettes smoked by ~40% (p=.002); Placebo group showed no change	Craving: No significant difference in craving between groups Anxiety: Both groups showed reduced anxiety over time (p=.04)	Positive (Significant reduction in consumption without increased craving)
Hindocha 2018a[75]	Laboratory; double-blind crossover; visual probe task (attentional bias)	30 individuals who smoke cigarettes (abstinent overnight)	800mg Oral CBD vs. Placebo	Attentional Bias: CBD reversed bias away from cues vs. placebo (p=0.007, d=0.704). Bias under CBD did not differ from satiated state (p=.82)	Pleasantness: CBD reduced explicit pleasantness of cigarette images (p=.011, d=0.514) Craving: CBD did not affect craving or withdrawal.	Positive (Reduces salience/pleasantness of cues, though not craving)
Hindocha 2018[52]	Laboratory; double-blind crossover; cognitive tasks	30 individuals with cigarette dependence who smoke cigarettes (abstinent overnight)	800mg Oral CBD vs. Placebo	Impulsivity: No effect on delay discounting (p=.801); Errors: CBD increased commission errors on Go/No-Go (p=.03); Memory: No effect on prose recall (p=.244)	Not reported	Neutral (No cognitive improvement during withdrawal)
Gournay 2024[53]	Open-label crossover; acute abstinence (4 hours)	20 individuals who use e-cigarettes daily	320mg Oral CBD vs. No CBD	Not reported	Withdrawal: CBD significantly reduced withdrawal severity (M=6.5) vs. No CBD (M=12) (p<.001); Anxiety: CBD reduced state anxiety (M=37.0) vs. No CBD (M=48.0) (p<0.001)	Positive (Reduces acute withdrawal severity and anxiety)
CB1 Receptor Antagonists / Inverse Agonists						

Robinson 2018[48]	Pooled analysis of 3 RCTs (STRATUS EU, US, META); double-blind, placebo-controlled; 10-week treatment + 40-week follow-up (EU/US only)	2,097 individuals who smoke cigarettes, motivated to quit (>9 cigs/day)	Rimonabant (CB1 inverse agonist) 20mg or 5mg vs. Placebo	Abstinence (EOT): 20mg significantly higher than placebo (SRNT prolonged: OR=1.61, 95% CI: 1.24-2.09; FDA continuous: OR=1.66, 95% CI: 1.23-2.23); 5mg did not differ from placebo. Abstinence (48 weeks): 20mg superior to placebo (OR=1.50, 95% CI: 1.03-2.17). Weight: 20mg reduced weight gain at EOT (-0.01 kg vs. +1.76 kg placebo, p<.0001); no difference at 48 weeks.	HADS: No significant difference in depression or anxiety change scores between groups.	Positive (Modest but significant efficacy for cessation at EOT and 48 weeks; weight benefit during treatment only; notable GI and anxiety-related adverse events)
Morrison 2010[50]	Outpatient RCT; 8-week treatment; safety and efficacy	317 individuals who had smoked cigarettes chronically (>10 cigs/day)	Taranabant (CB1 inverse agonist) titrated 2-8mg vs. Placebo	Abstinence: No difference in continuous abstinence (7.5% Taranabant vs 6.3% Placebo; OR=1.2, p=.678) Weight: Taranabant group lost weight (-1.6kg) vs Placebo gain (+0.6kg) (p<.001)	Adverse Events: Psychiatric AEs significantly elevated (43.4% vs. 26.6%, p=.002), including depression (8.2% vs. 2.5%, p=.043), irritability (17.6% vs. 5.7%, p=.001), and affect lability (5.0% vs. 0%, p=.007). GI AEs also elevated (49.7% vs. 19.0%, p<.001). PHQ-9 suicidal ideation: 5/156 taranabant vs. 0/155 placebo.	Negative (Ineffective for cessation; significant adverse side effects)

Study	Design	Population	Intervention	Efficacy Outcomes	Adverse Events/Other	Overall Effect
Tonstad & Aubin 2012[49]	Outpatient RCT; 8-week treatment; dose-ranging	810 individuals who smoke cigarettes (>10 cigs/day)	Surinabant (CB1 antagonist) 2.5, 5, or 10mg vs. Placebo	Abstinence: No difference in 4-week abstinence (21.5-22.6% Surinabant vs 25.2% Placebo; p=0.4); Weight: Dose-dependent reduction in gain (0.24kg for 10mg vs 1.19kg Placebo; p<.001)	Adverse Events: Overall psychiatric disorder rates similar to placebo (36.2–40.0% vs. 37.8%). Individual symptoms including insomnia (9.4–13.1% vs. 11.4%), anxiety (7.9–9.8% vs. 7.5%), and depression (3.5–5.9% vs. 4.0%) were numerically but not significantly higher at active doses. No suicidality signal.	Neutral (Ineffective for cessation; positive effect on weight)
**Acute Δ9-THC/Cannabis Effects on Tobacco Smoking**						

Kelly 1990[54]	Residential laboratory; 10-15 day isolation; within-subjects	8 male individuals who smoke cigarettes	Smoked cannabis (0%, 1.3%, 2.3%, or 2.7% Δ9-THC) 4x/day	Topography: Active cannabis significantly decreased tobacco smoking bouts (p<.05); Timing: Increased interval between cannabis use and next cigarette (p<.005)	Not primary focus	Positive (Acute cannabis suppressed tobacco smoking frequency)
Nemeth-Coslett 1986[55]	Laboratory; controlled acute administration; within-subjects	8 individuals who smoke cigarettes (30 cigs/day)	Smoked cannabis (0%, 1.3%, 2.8%, 4.0% Δ9-THC)	Topography: No significant alteration in number of cigarettes or puff duration following cannabis smoking	Ratings: Cannabis increased "drug effect" ratings (p<.001) but did not alter subjective ratings of tobacco cigarettes	Neutral (No effect on tobacco smoking behavior)
Peters 2021[56]	Laboratory; double-blind crossover; ad libitum smoking task	9 individuals who use nicotine and cannabis daily	Smoked Cannabis (5.2% Δ9-THC) vs. Placebo	Topography: No significant difference in total puff volume (p=.21), duration (p=.86), or velocity (p=.11)	Subjective: No significant difference in tobacco craving or subjective effects (e.g., "liking") after adjusting for baseline levels	Neutral (No uniform effect on tobacco intensity or subjective reward)

Study	Design	Sample	Intervention	Primary Outcome	Secondary Outcome	Conclusion
Gorey 2024[58]	Naturalistic (Coffeeshop); double-blind crossover; implicit association	85 individuals who use nicotine and cannabis	Smoked joint (Δ9-THC vs. Placebo)	Implicit Bias: No effect of cannabis on approach/avoidance bias for tobacco (p=.21); Behavior: Baseline motivation did not predict use at 6-month follow-up (p=.94)	Avoidance: Explicit tobacco avoidance decreased in *both* active (p<.001) and placebo (p<.001) conditions	Neutral (No pharmacological "gateway" effect; setting reduces avoidance)
Co-Use Interactions (Mechanisms, Withdrawal & Relapse)						
Herrmann 2019[61]	Laboratory + Inpatient; double-blind; relapse model	46 individuals who use nicotine and cannabis	Outpatient: Varenicline vs. Placebo; Inpatient: Nabilone vs. Placebo	Tobacco: Varenicline increased tobacco abstinence rates (46% vs 24%, p=.001); Cannabis: Nabilone did not reduce cannabis relapse inhalations (p>.05)	Withdrawal: Nabilone attenuated cannabis withdrawal (e.g., irritability p<.05); Craving: Varenicline reduced cigarette craving (p<.05)	Mixed (Varenicline helped tobacco cessation; Nabilone helped withdrawal but not cannabis relapse)
Hindocha 2017a[76]	Laboratory; double-blind crossover; memory tasks	24 non-dependent individuals who use nicotine and cannabis	Cannabis (Active/Placebo) + Tobacco (Active/Placebo) in joints	Memory: Tobacco offset cannabis-induced impairment in delayed recall (p=.037, d=0.5); Working Memory: Tobacco improved correct responses (p=.037)	Psychotomimetic: Tobacco did not alter ratings of "stoned," "dizzy," or PSI scores induced by cannabis (p>.05)	Interaction (Tobacco mitigates some cannabis-induced cognitive deficits)
Hindocha 2017b[77]	Laboratory; double-blind crossover; purchase tasks	24 non-dependent individuals who use nicotine and cannabis	Cannabis (Active/Placebo) + Tobacco (Active/Placebo) in joints	Demand: Active cannabis reduced cigarette breakpoint (p=.01); Response Time: Cannabis slowed RT to all stimuli except cigarette cues (p=.02)	Liking: Cannabis reduced liking of cannabis stimuli (p=.01); Tobacco had no effect on liking/craving (p>.05)	Interaction (Acute cannabis reduced motivation/demand for tobacco; Tobacco did not increase cannabis reward)
Penetar 2005[57]	Laboratory; double-blind crossover; acute administration	20 individuals who smoke cigarettes (10M/10F)	Transdermal Nicotine (21mg) + Smoked Cannabis (2% or 3.5% Δ9-THC)	Physiological: Nicotine enhanced cannabis-induced heart rate increases (Mean increase 58 vs 45 bpm; p<.001)	Subjective: Nicotine enhanced "Stimulated" ratings and ARCI Amphetamine scale after cannabis (p=.01)	Synergistic (Nicotine enhances physiological and stimulant effects of cannabis)

Vandrey 2008[59]	Within-subject ABACAD design; 5-day abstinence periods	12 individuals with heavy nicotine and cannabis use	Abstinence from: Cannabis, Tobacco, or Both	Not applicable	Withdrawal: Dual abstinence scores (e.g., aggression) higher than single on Day 2; Discomfort: Varied preference (5 rated dual hardest, 5 rated dual easiest)	Negative (Dual abstinence can increase withdrawal severity, though not uniformly)
al'Absi 2024[78]	Laboratory; stress reactivity task	79 participants (Nicotine only, Cannabis only, individuals who use nicotine and cannabis, individuals who don't use any)	15h Nicotine abstinence vs. Ad libitum use	BP/HR: individuals who use nicotineshowed blunted systolic BP response; Individuals who use cannabis showed exaggerated diastolic BP (p=.03)	Craving: Individuals who use nicotine and cannabis had higher cannabis craving than individuals who use cannabis only (p<.01); Affect: individuals who use nicotine reported less positive affect (p<.05)	Negative (Nicotine withdrawal in individuals who use nicotine and cannabis may heighten cannabis craving and alter stress response)
Haney 2013[60]	Inpatient; within-subject crossover (Study 2)	15 individuals who smoke cigarettes and cannabis daily	Smoking As Usual (SAU) vs. Tobacco Quit (abstinence)	Relapse: Tobacco status did not influence cannabis relapse (93% SAU vs 87% Quit relapsed; number of puffs identical)	Withdrawal: Tobacco status did not alter cannabis intoxication or withdrawal symptoms (p>.05)	Null (Acute tobacco abstinence does not improve cannabis relapse outcomes)
Parker 2018[62]	Laboratory; double-blind crossover; reduced nicotine cigarettes (RNCC)	169 individuals who smoke cigarettes (63 individuals who use cannabis)	RNCCs (0.4 to 15.8 mg/g nicotine)	Reinforcement: Cannabis use status did not moderate nicotine dose effect on choice (p=.55) or demand (p>.05)	Subjective: Individuals who use cannabisreported higher "Smoking Satisfaction" (p=.002) across all doses	Null (Cannabis use does not interfere with the efficacy of reduced nicotine cigarettes)

Figure 1. Endocannabinoid–Nicotinic Convergence in Mesolimbic Reward Circuitry.

(A) Schematic highlighting co-localization of nicotinic acetylcholine receptors (nAChRs) and cannabinoid type-1 receptors (CB1R) across key nodes implicated in tobacco reinforcement and relapse vulnerability: prefrontal cortex (PFC; salience attribution/executive control), ventral tegmental area (VTA; nicotine-driven dopaminergic firing), nucleus accumbens (NAc; phasic dopamine [DA] encoding reinforcement), and amygdala (stress/negative affect). The CB1R ligand spectrum (inset) illustrates how different compounds engage CB1R with varying directionality and magnitude, from full agonists (e.g., WIN 55,212-2) and partial agonists (Δ9-THC) that activate the receptor, to negative allosteric modulators (CBD) that attenuate receptor signaling without suppressing constitutive activity, to inverse agonists (rimonabant, taranabant, surinabant) that suppress both agonist-driven and constitutive CB1R signaling. **(B)** VTA dopamine synapse model illustrating nicotine activation of α4β2* nAChRs, nicotine-evoked DA signaling, and activity-dependent synthesis of endocannabinoids (anandamide [AEA] and 2-arachidonoylglycerol [2-AG]). Endocannabinoids act as retrograde signals to activate presynaptic CB1R, suppressing GABA release and disinhibiting DA neurons. Endocannabinoid tone is terminated by fatty acid amide hydrolase (FAAH; AEA) and monoacylglycerol lipase (MAGL; 2-AG). Arrows indicate facilitation/activation; blunt lines indicate inhibition.

Figure 2. Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA)

Flowchart Diagram.

Flow diagram illustrating the study selection process. A total of 9,413 records were identified across four databases. After removing 4,544 duplicates, 4,869 records were screened by title and abstract, and 216 full-text articles were assessed for eligibility. 52 studies met inclusion criteria: 18 observational, 15 preclinical, and 19 clinical.

Figure 3. Forest Plot of the Association Between Cannabis Use and Tobacco Cessation

Outcomes in Observational Studies

Random-effects meta-analysis of 18 observational studies (20 independent estimates; N=229,630) examining the odds of tobacco cessation among people who use cannabis compared to people who do not use cannabis. The pooled odds ratio was 0.65 (95% CI: 0.55-0.78; p<0.0001), indicating 35% lower odds of cessation among people who use cannabis. Between-study heterogeneity was high (I²=88.1%; p<0.0001). Individual study estimates are represented by squares (proportional to study weight), with horizontal lines indicating 95% confidence intervals. The diamond represents the pooled effect estimate.
