Summary: In a multicenter retrospective cohort study, we show that the real-world clinical impact of plasma metagenomic next-generation sequencing (mNGS) for the noninvasive diagnosis of infections is limited (positive impact 7.3%). Further studies are needed to optimize the impact of mNGS.

Abstract

Background: Metagenomic next-generation sequencing (mNGS) of plasma cell-free DNA has emerged as an attractive diagnostic modality allowing broad-range pathogen detection, noninvasive sampling, and earlier diagnosis. However, little is known about its real-world clinical impact as used in routine practice.

Methods: We performed a retrospective cohort study of all patients for whom plasma mNGS (Karius test) was performed for all indications at 5 U.S. institutions over 1.5 years. Comprehensive chart review was performed, and standardized assessment of clinical impact of the mNGS based on the treating team's interpretation of Karius results and patient management was established.

Results: A total of 82 Karius tests were evaluated, from 39 (47.6%) adults and 43 (52.4%) children and a total of 53 (64.6%) immunocompromised patients. Karius positivity rate was 50/82 (61.0%), with 24 (48.0%) showing two or more organisms (range, 2-8). The Karius test results led to positive impact in 6 (7.3%), negative impact in 3 (3.7%), no impact in 70 (85.4%), and was indeterminate in 3 (3.7%). Cases with positive Karius result and clinical impact involved bacteria and/or fungi but not DNA viruses or parasites. In 10 patients who underwent 16 additional repeated tests, only one was associated with clinical impact.

Conclusions: The real-world impact of the Karius test as currently used in routine clinical practice is limited. Further studies are needed to identify high-yield patient populations, define the complementary role of mNGS to conventional microbiological methods, and how best to integrate mNGS into current testing algorithms.

Introduction

Metagenomic next-generation sequencing (mNGS) of pathogen nucleic acid in clinical samples has emerged as a promising one-test approach for hypothesis-free diagnosis of potentially all infectious etiologies. mNGS is currently orderable in select reference laboratories from plasma cell-free DNA (Karius, Redwood City, CA), from DNA and RNA in cerebrospinal fluid (CSF) (University of California, San Francisco) and DNA and RNA in respiratory secretions (IDbyDNA, San Francisco, CA) [1]. Of these, the Karius test has been commercially available the longest and is likely the most common mNGS send-out test in U.S. institutions. This assay is reported to detect and quantify pathogen cell-free DNA from 1,250 bacteria, DNA viruses, fungi and eukaryotic parasites [2], and has been employed for the diagnosis of invasive fungal disease [3, 4], community-acquired pneumonia [5] and infections in immunocompromised hosts [6, 7].

The availability of clinical metagenomic cell-free DNA sequencing has generated interest from clinical providers across disciplines given the noninvasive nature of testing, and the potential to pose an actionable diagnosis faster than through conventional microbiologic methods. However, little is known about the clinical impact of mNGS testing when used for routine patient care. A study assessing the clinical impact of mNGS from CSF in patients with suspected meningitis and encephalitis showed positive clinical impact in 8/204 (3.9%) patients tested [8]. In the present multicenter study, our aim was to comprehensively examine the real-world clinical impact of the Karius test ordered for all indications for the diagnosis of infectious diseases.

Methods

Ethics. This study was approved by the Institutional Review Boards (IRB) at Stanford University and Columbia Medical Center (CUMC). IRB was waived for this project for University of California Los Angeles (UCLA), University of Utah (UT) and Children's Hospital of Los Angeles (CHLA).

Karius Test. The Karius laboratory started to offer commercial testing in December 2016. Plasma from whole blood collected in a K2-EDTA or BD Vacutainer PPT tube (Becton Dickinson, Franklin Lakes, NJ) and separated <6 hours after draw was sent either fresh (within 4 days of blood draw) or frozen. All testing was performed by Karius per routine testing protocol as previously described [2].

Study Design. We performed a retrospective cohort study of patients for all consecutive plasma mNGS samples sent-out for Karius test from 5 U.S. institutions (CHLA, CUMC, Stanford Health Care, UCLA and UT) from August 1st 2017 to May 31st 2019. Comprehensive chart review was performed by each site investigator for respective patients, and clinical impact solely based on the treating team's interpretation of Karius results and their subsequent management decisions was assessed according to predefined objective grading criteria (Table 1) as to whether Karius test result had a positive, negative, or no clinical impact, or if impact was indeterminate. This study intended to assess the real-world impact of Karius test and therefore only the treating team's decisions and actions were considered for impact assessment, and no retrospective clinical consensus assessment of impact and adjudication by a panel of

experts was performed. Given that Karius testing may be reordered in the same patient for different reasons including patient monitoring, the main analysis was performed on the first Karius test per patient. A separate analysis was performed on repeat tests.

Statistical Analysis. Statistical analysis was performed with Stata 15 (Stata Corp, TX, USA). Due to the descriptive nature of the review, a formal sample size calculation was not performed.

Results

A total of 82 Karius tests were performed in unique patients cared for at UCLA ($n=50$ tests), SHC ($n=21$), CUMC ($n=5$), UT ($n=3$) and CHLA ($n=3$) (Table 2). There were 39 (47.6%) adults and 43 (52.4%) children, 52 (63.4%) males and 53 (64.6%) immunocompromised patients, most commonly solid organ transplant (17.1%) and primary immunodeficiency (13.4%) (Table 2). The mean turn-around-time from sample collection to result was 3.1 days (SD: 1.2), and the most common ordering providers were infectious disease physicians (74.4%), followed by oncologists (11.0%). The main indication for testing was fever of unknown origin (23.2%), suspected respiratory infection (13.4%), sepsis (9.8%), suspected endocarditis (8.5%) and febrile neutropenia (7.3%). The Karius positivity rate was 50/82 (61.0%), with 26 (52.0%) of these tests resulted as monomicrobial (18 bacterial, 5 viral and 3 fungal), and 24 (48.0%) showing 2 or more organisms (range, 2-8). There was no parasite detected in this cohort.

The Karius test results led to positive or negative clinical impact in 9 (11.0%) tests. The impact was positive in 6 (7.3%) and negative in 3 (3.7%) (Table 3). Of these 9 Karius tests, 8 had organisms detected while 1 had no organism detected. Impact was none in 70 (85.4%) tests and indeterminate in 3 (3.7%). All 8 cases with positive Karius result and clinical impact involved bacteria and/or fungi; determination of the presence or absence of DNA viruses by plasma mNGS demonstrated no clinical impact in this study. Positive clinical impact was categorized as de-escalation of therapy ($n=1$), earlier diagnosis than conventional methods and initiation of appropriate therapy ($n=2$), new diagnosis not made by conventional methods and escalation of therapy ($n=1$), and new diagnosis and de-escalation ($n=2$). The 3 new diagnoses made by Karius test included presumptive diagnosis of an abdominal aorta mycotic aneurysm, a diagnosis of *Rhizopus oryzae* confirming disseminated mucormycosis, and identification of mixed oral flora in a case of blood culture-negative endocarditis, facilitating de-escalation of therapy. The 3 cases associated with negative clinical impact resulted in additional, unnecessary diagnostic investigations ($n=2$), and unnecessary treatment ($n=1$).

A total of 25/82 (30.5%) tests underwent Karius testing with a pre-established microbiological diagnosis, with relative proportions varying by institution from 0 to 40%. The most common conventional diagnostic method establishing a microbiological diagnosis in this group was blood culture ($n=9$), tissue bacterial culture ($n=6$) and viral blood-based PCR ($n=4$). Of the 25 patients with a positive conventional diagnosis, 16 (64.0%) showed the same organism detected by the Karius test, with 7 of these showing other organisms in addition to the one that was reproducibly detected. The remaining 9

cases where Karius did not reproduce the result from conventional microbiological testing included bacteria (*Streptococcus viridans* (n=1), *Mycobacterium haemophilum* (n=1), *Mycobacterium chelonae* (n=1), *Mycobacterium bovis* (n=1)), DNA virus (adenovirus (n=1)), and fungi (*Candida parapsilosis* (n=1), *Candida lusitanae* (n=1), *Coccidioides immitis/posadasii* (n=1), Mucorales (n=1)).

A subset of 10 patients underwent repeat testing, for a total of 16 additional repeated tests from UCLA (n=14), SHC (n=1) and CUMC (n=1). Review of the 16 repeat tests revealed 1 case associated with a positive clinical impact, where the repeat Karius test was performed 3 months after the initial one. This 2-year-old boy with a history of heart transplant was tested by Karius test shortly after an episode of *Stenotrophomonas maltophilia* bacteremia and positive respiratory cultures for the same organism. Karius testing confirmed *Stenotrophomonas maltophilia* and did not identify any other organism which prompted the team to de-escalate therapy.

Discussion

Metagenomic next-generation sequencing has stimulated much interest among providers across medical subspecialties given its potential for broad-range pathogen detection. Furthermore, the noninvasive nature of plasma samples makes mNGS an attractive diagnostic modality for deep-seated infections that currently require invasive biopsy. However, the value of mNGS testing as a diagnostic tool is poorly understood. In this multicenter retrospective cohort study, we show that, as currently used in clinical practice, the real-world clinical impact of the Karius test is limited given that it resulted in

no or negative impact in the majority (92.7%) of patients. This finding was consistent with that reported for mNGS on CSF where 196 of 204 (96.1%) tests did not have a clinical impact [8]. As it currently stands, in most academic and private health systems, microbiology and virology diagnostic laboratories offer a comprehensive menu of culture-based and molecular tests such that only few, typically complex, cases with infectious etiology will be left without a diagnosis. Important questions to consider now are whether mNGS has the diagnostic accuracy required to complement currently-available diagnostics, and how best to integrate mNGS into current testing algorithms. Published studies indicate CSF and plasma mNGS assays lack sensitivity compared to conventional methods and therefore cannot be used as stand-alone or rule-out tests [2, 8]. Thus, options include reserving mNGS as last resort for cases for which conventional microbiological testing has failed to provide an answer, or in some cases to consider more proximal testing in parallel to conventional tests. The decision to include mNGS testing should take into account the differential diagnosis, as well as the availability and accuracy of conventional methods. The specific example of lack of clinical impact of positive Karius results for DNA viruses in this cohort provides a compelling case for routine highly-available, highly-accurate molecular virology assays providing sufficient and actionable diagnostic information prior to Karius testing.

Plasma cell-free DNA may originate from the site of infection or colonization. Although Karius reports quantitative units, there is no threshold that distinguishes colonization from infection, and interpretation of results may therefore be clinically challenging, especially in immunocompromised hosts and patients with disrupted

intestinal barrier. Clinical validation data recently reported on the Karius test from patients presenting to the emergency department at a tertiary hospital with suspected sepsis have demonstrated a positive percent agreement of 84.8% and negative percent agreement of 48.2% compared to all microbiological reference testing [2]. The finding that only 6 of 65 (9.2%) positive test results were positively impactful in the current study is consistent with an assay specificity that is insufficient to enable clinical impact when organisms are detected under routine practice. Even in certain cases where care was tailored to the positive Karius result, it is unclear if the reported organisms were the underlying drivers of pathology. For example, the patient with abdominal aorta mycotic aneurysm (Table 3; Study ID SHC-11) in whom antibiotic therapy was de-escalated to chronic suppressive therapy with amoxicillin-clavulanic acid based on a positive Karius result with *Enterococcus faecalis* and *Prevotella melaninogenica* presented with multiple clinical recurrences of back pain and eventually grew *Mycobacterium avium* complex (MAC) from a vertebral tissue biopsy 9 months later.

Patient selection practices may also have contributed to low clinical impact as almost one-third (ranging from 0 to 40% by institution) of patients had already received a microbiological diagnosis prior to testing. The only case in this cohort to have demonstrated clinical impact in the setting of a pre-established microbiological diagnosis is that of the repeat Karius test identifying *Stenotrophomonas maltophilia* only in a patient with known bacteremia with the same organism, leading to de-escalation of therapy. This highlights the important role of diagnostic stewardship in optimizing testing algorithms and preventing unnecessary testing. In situations where positive conventional test results

precede the mNGS result, patient management (i.e., escalation or de-escalation of therapy) should be considered based on conventional microbiological diagnostics rather than waiting for confirmatory mNGS result.

The finding that 6/82 (7.3%) of Karius test results in this study led to positive clinical impact is in contrast to that recently reported in a single pediatric center in Chicago where 56/100 (56.0%) test results were considered clinically actionable [9]. This discrepancy may have been driven by differences in patient selection, in addition to differences in outcome assessment methodology. For instance, in our study, clinical impact was solely based on the treating team's interpretation of Karius results and their subsequent management decisions; in contrast, in the above study, clinical adjudication was performed where 'clinical relevance' was unclear from the medical record. Inherent inter-provider interpretation differences of whether Karius results represent a clinically significant pathogen or colonization also likely contributed to findings. Other differences between studies included variability in testing indication, proportion of ordering infectious diseases providers, and proportion of patients with a known microbiological diagnosis pre-Karius testing. The low clinical impact proportion in the present study was closer to that reported for mNGS on CSF where 8/204 (3.9%) of tests led to positive clinical impact [8].

This study was strengthened by its multicenter design including 5 adult and pediatric sites, and by its assessment of real-world practice in presenting data from provider-initiated testing. However, there are limitations. Firstly, although we made

significant effort to standardize the definition and application of clinical impact criteria, some of the cases included were very complex medically and interpretation of clinical impact may have been challenging to ascertain. The definition of impact was based on how providing physicians interpreted and reacted to test results. This may have over or underestimated the real impact of the Karius test result. Further studies with more comprehensive and objective measures of impact (for example, including antibiotic use, hospital length-of-stay, laboratory testing utilization) are needed to accurately quantify clinical impact. Secondly, approval criteria for send-out testing varied by institution and time period such that patient populations may have varied in their pre-test probability which may have influenced the assessment of clinical impact. Finally, given this was a convenience sample, not all patient populations are represented equally. For example, only one HIV-1-positive individual was included, which limits generalizability to this patient population.

In conclusion, plasma mNGS represents an attractive diagnostic modality due to its noninvasive nature and potential to provide an early and actionable diagnosis. However, this study has shown that the real-world impact of the Karius test as currently used in clinical practice is limited given that this testing resulted in no or negative impact in the majority (92.7%) of patients. Further studies are needed to better understand which patient populations may potentially benefit, define the complementary role of mNGS to conventional microbiological methods, and improve diagnostic interpretation algorithms. Furthermore, institutions should adopt an active diagnostic stewardship role to ensure optimal use of mNGS.

Table 1. Standardized criteria to assess clinical impact of the Karius test per the treating team.

Category of clinical impact	Change in management	Clinical impact type
Positive	Yes	New diagnosis based on Karius result and not confirmed by conventional microbiological methods
		Earlier diagnosis based on Karius result and later confirmed by conventional microbiological methods
		Karius result enabled avoidance of invasive surgical biopsy
		Karius result enabled initiation of appropriate therapy
		Karius result enabled de-escalation of therapy
		Karius result enabled escalation of therapy
	No	Karius result confirmed clinical diagnosis
Negative	Yes	Karius result led to unnecessary treatment
		Karius result led to additional unnecessary diagnostic investigations
		Karius result led to longer length-of-stay
None	No	Karius result showed new organism but result not acted upon

		Karius result confirmed conventional microbiological diagnosis and not acted upon
		Patient died before Karius result available
Indeterminate	Yes	Could not determine clinical impact from chart review
	No	
	Indeterminate

Table 3. Clinical data for cases with clinical impact after Karius test result.

Study ID	Age/sex	Comorbidities	Clinical syndrome	Karius test result (molecules per microliter)	Clinical impact per treating team	Clinical impact type	Detail
SHC-11	57M	HIV/AIDS, CAD, CKD	Suspected mycotic aneurysm	<i>Enterococcus faecalis</i> (344) <i>Prevotella melaninogenica</i> (176)	Positive	New diagnosis and de-escalation of therapy	Karius test result was used to de-escalate chronic suppressive therapy to amoxicillin-clavulanic acid, after a 6-week course of empiric vancomycin and ceftriaxone. Nine months later, after multiple clinical recurrences, vertebral tissue biopsy grew <i>Mycobacterium avium</i> complex.
SHC-13	47F	s/p combined heart and kidney transplant (2018) for anthracycline-induced cardiomyopathy, history of ALL	Acute flaccid paralysis (AFP)	<i>Aspergillus fumigatus</i> (qualitative result)	None/ Positive	None for AFP. Earlier diagnosis and initiation of therapy for fungal infection	Karius test identified <i>Aspergillus fumigatus</i> earlier than conventional methods and prompted chest imaging and respiratory cultures that confirmed invasive pulmonary aspergillosis. Serum galactomannan had been

							elevated (>2.00) in the week prior to Karius test.
UCLA-3	2M	Idiopathic acute liver failure, aplastic anemia, HLH	Recurrent fever	<i>Candida tropicalis</i> (6,670)	Positive	Earlier diagnosis and initiation of therapy	Karius test result was used to initiate antifungal therapy with caspofungin 5 days earlier than the time of diagnosis by blood culture.
UCLA-20	10F	Liver/small bowel/colon/pancreas transplant (2018), TPN-dependent short gut syndrome	Jejunal perforation with necrotic fascia, subcutaneous abscess, perinephric fluid collection	<i>Rhizopus oryzae</i> (169,935) <i>Stenotrophomonas maltophilia</i> (2,649) <i>E. coli</i> (234)	Positive	New diagnosis not made by conventional methods and escalation of therapy	Karius test diagnosed invasive mucormycosis, which was not made through conventional methods and which enabled targeted antifungal therapy. The patient was not treated for the bacterial organisms detected.
UCLA-47	6wk-old M	Newborn by emergency caesarean section, TAPVR s/p repair	Multi-organ dysfunction syndrome, coagulopathy, respiratory failure	Negative	Positive	De-escalation of therapy	Karius test result was negative and supported the clinical suspicion that patient's clinical decompensation was not infectious in etiology. This prompted discontinuation of empiric cefepime.

UT-2	75M	Metastatic carcinoma of unknown primary	Multifocal abscesses (lung, liver and kidney)	<i>Streptococcus parasanguinis</i> (372) <i>Morococcus cerebrosus</i> (212) <i>Neisseria sicca</i> (96) <i>Veillonella parvula</i> (64) <i>Prevotella melaninogenica</i> (36) <i>Propionibacterium acidifaciens</i> (24) EBV (23)	Positive	New diagnosis not made by conventional methods and de-escalation of therapy	Karius test identified mixed oral flora, which was consistent with a periodontal source of infection. This allowed narrowing of antibacterial therapy from vancomycin/piperacillin-tazobactam to amoxicillin-clavulanic acid for a total duration of 6 weeks of therapy.
CUMC-5	17F	GATA2-MDS s/p PBSC transplant (2018)	Fever, buccal lesions, hepatic lesions	<i>Trichosporon asahii</i> (1,786) <i>Enterococcus faecium</i>	Negative	Unnecessary treatment	Karius test result prompted additional antibacterial coverage that was not thought to be warranted per ID team. Patient

				(1,567) <i>Mucor indicus</i> (1,199) CMV (763) <i>Rhizopus delemar</i> (107) <i>Candida glabrata</i> (75) <i>Veillonella parvula</i> (47)			was already known to have invasive mucormycosis.
SHC-8	39F	CVID	Chronic low-grade fever	<i>Prevotella bivia</i> (23) <i>Streptococcus pseudopneumoniae</i> (23) <i>Bacteroides fragilis</i> (21)	Negative	Additional diagnostic investigations	Karius test result prompted an ED visit, and subsequent outpatient consultation with ID to outline management. The patient was not treated for the Karius test result.
SHC-14	20M	Refractory and recurrent marginal cell MALT-like lymphoma of ileum and colon	Investigation of lymphoma etiology	<i>Trichoderma atroviride</i> (695)	Negative	Additional diagnostic investigations	Karius test result prompted concern by the treating team about a false positive result. Targeted fungal sequencing on

				<i>Enterobacter cloacae</i> complex (96)			plasma was performed to try to disprove result and was negative. The patient was not treated for the Karius test result.
