Short running title: Multiomics heterogeneity in Alzheimer’s

NOTE: This preprint reports new research that has not been certified by peer review and should not be used to guide clinical practice.
Abstract

Etiological and clinical heterogeneity is increasingly recognized as a common characteristic of Alzheimer's disease and related dementias. This heterogeneity complicates diagnosis, treatment, and the design and testing of new drugs. An important line of research is discovery of multimodal biomarkers that will facilitate the targeting of subpopulations with homogeneous pathophysiological signatures. High-throughput 'omics' are unbiased data driven techniques that probe the complex etiology of Alzheimer's disease from multiple levels (e.g. network, cellular, and molecular) and thereby account for pathophysiological heterogeneity in clinical populations. This review focuses on data reduction analyses that identify complementary disease-relevant perturbations for three omics techniques: neuroimaging-based subtypes, metabolomics-derived metabolite panels, and genomics-related polygenic risk scores. Neuroimaging can track accrued neurodegeneration and other sources of network impairments, metabolomics provides a global small-molecule snapshot that is sensitive to ongoing pathological processes, and genomics characterizes relatively invariant genetic risk factors representing key pathways associated with Alzheimer's disease. Following this focused review, we present a roadmap for assembling these multiomics measurements into a diagnostic tool highly predictive of individual clinical trajectories, to further the goal of personalized medicine in Alzheimer's disease.

Keywords
Alzheimer's disease, multiomics biomarkers, neuroimaging subtype, metabolite panel, polygenic risk score

lvPPA logopenic progressive aphasia
MAF minor allele frequency
MCI mild cognitive impairment
NDDs neurodegenerative diseases
NGS next-generation genome sequencing
PCA posterior cortical atrophy
PET positron emission tomography
PRS polygenic risk score
SNPs single nucleotide polymorphisms
Introduction

Alzheimer's disease is a complex, multifactorial pathology that manifests itself along a continuum of conditions, ranging from asymptomatic, to mild cognitive impairment (MCI), to dementia (specifically Alzheimer's disease dementia). Trials of disease-modifying therapies remain unsuccessful, and these persistent failures have been attributed to (1) intervention late in the disease process (i.e. symptomatic stage), by which time extensive irreversible damage has accrued, and (2) lack of precision intervention targets in a multifactorial condition. Accordingly, an important line of current research is directed at the discovery of multimodal biomarkers that will help facilitate the detection of Alzheimer's disease in asymptomatic populations, and the adaptation of intervention regimens to different target subpopulations in prevention trials (Anstey et al., 2015; Olanrewaju et al., 2015). This work reviews recent data-driven approaches to biomarker discovery, in three omics fields that capture complementary aspects of neurodegeneration and Alzheimer's disease risk factors. We further propose a roadmap for integrating these multiomics biomarkers to advance our understanding of heterogeneity in Alzheimer's disease, and promote efficacy in intervention trials.

Established Alzheimer's disease biomarkers currently capture three facets of the disease pathophysiology: amyloidosis, tauopathy, and specific aspects of neurodegeneration (Jack et al., 2018). Although these biomarkers have been usefully applied to the crucial goal of early Alzheimer's disease detection (Sperling et al., 2011), they fall short in explaining the heterogeneity of individual clinical trajectories, and their ability to predict differential cognitive decline is modest (Dumurgier et al., 2017). Predicting progression to dementia is challenging, as patients diagnosed with probable Alzheimer's disease dementia show considerable heterogeneity in the cognitive domains impaired (Scheltens et al., 2016), and the presence or severity of established Alzheimer's disease biomarkers. For example, amyloidosis-and-tauopathy-defined ‘pure Alzheimer's disease neuropathology’ is observed in only 30-50 percent of patients with probable Alzheimer's disease dementia (Beach et al., 2012; Robinson et al., 2018). The remaining cases show co-occurrence of multiple brain pathologies that overlap with other NDDs of aging, such as cerebral small vessel disease, and Lewy body dementia. Minimum to above-threshold levels of Alzheimer's disease pathology are also observed in a considerable proportion (39%) of dementia patients not clinically diagnosed as probable Alzheimer's disease (Beach et al., 2012). Alzheimer's disease pathology has also been demonstrated in postmortem studies of CN older adults (Bennett et al., 2006), and it remains
unclear if such individuals would have developed Alzheimer's disease symptoms with time, should they have lived longer (Jagust, 2013). Overall, “top-down” clinical labels, based primarily on cognitive symptoms, imperfectly align with biomarkers of neurodegeneration. Additional biomarkers are thus urgently needed to characterize the clinico-pathological heterogeneity of Alzheimer's disease, and to disambiguate it from other age-related NDDs and normal aging (Jack et al., 2018).

A radically different paradigm to NDDs is to move away from “top-down” clinical labels, and concentrate on pathological signatures built “bottom up”, using unsupervised machine learning algorithms and high-throughput ‘omics’ metrics that screen global facets of an organism. These data-driven approaches provide new opportunities to probe the complex etiology of Alzheimer's disease from multiple levels (example network, cellular, and molecular), and to identify biomarker signatures with high diagnostic/prognostic value. This review focuses on the following omics approaches: brain connectomics, metabolomics, and genomics. These omics data capture complementary information on Alzheimer's disease emergence and progression: brain connectomics (and morphometry) can track accrued neurodegeneration and other sources of network impairments, metabolomics provides a global small-molecule snapshot that is sensitive to ongoing pathological processes, and genomics characterizes relatively invariant genetic risk factors representing key pathways associated with Alzheimer's disease (Jack et al., 2018). The high-dimensional nature of omics “big data” can prove challenging to process, manipulate, and visualize, even when a single modality is involved. Multiple redundancies are often present in these measures, and not all data points provide independent information as they tend to covary due to shared biological processes. We focus this review on three omics data reduction techniques that capture disease-relevant population heterogeneity with a limited number of indicators: neuroimaging-based subtypes, metabolite panels, and polygenic risk score or PRS. Neuroimaging subtypes are based on data-driven algorithms that identify patient subgroups with homogeneous brain imaging features. Metabolite panels are developed via data-driven algorithms applied to thousands of small molecules representing global biochemical events and distinguishing clinical phenotypes. PRS and other empirically derived representations of interactive or multi-gene risk may represent key domains of mechanisms and pathways to Alzheimer's disease. Following this focused review, we discuss the rationale and challenges for assembling multiomics diagnostic tools highly predictive of individual clinical trajectories, and in particular, the importance of pathophysiological heterogeneity in research clinical cohorts.
Materials and Methods

We conducted parallel focused reviews of PubMed articles published between January 2011 to June 2018 in three omics domains: brain connectomics (and morphometry), metabolomics, and genomics. We included studies investigating Alzheimer's disease in human and published in English. Additional articles (that met criteria) were identified by scanning the reference lists of selected PubMed articles. Described in the following three sections are search characteristics specific to each omics domain. We have provided in Supplementary Material (Supplementary Tables S1, S2, and S5) characteristics of the 40 domain-specific omics studies included.

Brain morphology and connectomics

Search term combinations used for brain morphology and connectomics in neuroimaging are provided in were: (1) alzheimer’s disease OR alzheimer pathology AND subtype, (2) mild cognitive impairment OR amnestic mild cognitive impairment OR MCI OR amnestic MCI AND hierarchical clustering; resting-state AND functional MRI AND alzheimer AND clustering, (3) alzheimer’s disease OR alzheimer pathology AND structural subtype, (4) alzheimer’s disease OR alzheimer pathology AND structural MRI AND clustering, (5) resting-state AND functional MRI AND alzheimer AND hierarchical clustering, (6) diffusion MRI AND alzheimer AND clustering, (7) diffusion MRI AND alzheimer AND hierarchical clustering. To these we applied the “common” exclusion criteria. Thereafter, only studies reporting AD spectrum subgroups identified using data-driven methods were included. It should be noted that neuroimaging-based subtyping is an emergent field and there is still a lack of consistent terminology. Therefore, to avoid missing relevant studies due to stringent use of terminology, search combinations 1 and 2, used relaxed and inclusive keywords, which captured all of the morphometry based literature. In total, 12 papers met our criteria, and were reviewed.

Metabolomics

Search term combinations for metabolomics were: (1) alzheimer’s disease AND metabolomics panels; (2) alzheimer’s disease AND metabolomics profiles; (3) alzheimer’s disease AND metabolomics networks; (4) alzheimer’s disease AND metabolomics pathways; (5) alzheimer’s disease AND metabolomics biomarkers. To these we applied the common exclusion criteria. We further excluded: reviews and technical reports; articles not relevant to AD metabolomic panels, pathways, or networks; and studies using a targeted metabolomics
approach. Five papers were identified from reference list scans. In total, 11 studies were reviewed. Details on key metabolites highlighted in the 11 studies were compiled from three different databases: Kyoto Encyclopedia of Genes and Genomes (KEGG, https://www.genome.jp/kegg/pathway.html) Pathway Database, Human Metabolome Database (HMDB, http://www.hmdb.ca/) and PubMed. These details were used to generate Fig. 2b and are provided in Supplementary Table S3.

Genomics

Search term combinations used for the genomics were: (Polygenic Risk Scale OR Polygenic Risk Index OR Genetic Risk Score OR Genetic Risk Scale OR Genetic Risk Index) AND (Alzheimer Disease OR Alzheimers Disease OR Alzheimer's Disease), which identified 264 potential papers. To these we applied the “common” exclusion criteria, followed by exclusion of single-gene studies. In total 17 studies were reviewed. References used for the compilation of the genes in Supplementary Table S4 are provided in the Supplemental Reference section.
Brain Subtypes

**Figure 1: Brain morphology and connectomics Alzheimer's disease-related subtypes**

Neuroimaging provides insight into the effect of neurodegeneration on brain health. There exist different tools that can capture distinct, yet complementary, aspects of brain structure and function. The most established neuroimaging marker of neurodegeneration is grey matter atrophy, measured by structural MRI. Structural MRI is a non-invasive technique widely used in both research and clinical practice. To generate structural maps, individual structural MRI scans are first spatially aligned to a reference template or atlas (1a). Then for each individual and each voxel (smallest volume element in MRI data), a metric characterizing the local structure of the grey matter is generated (1a), such as grey matter volume, cortical thickness or surface area. Using these approaches, it is possible to monitor the thinning of grey matter, which likely reflects the death of neuronal cell bodies at advanced stages of neurodegeneration.

Synaptic disruption is an early event in Alzheimer's disease (Sperling et al., 2011), and functional networks may have the ability to compensate the impact of neurodegeneration on
cognitive symptoms (Franzmeier et al., 2017). For these reasons, intrinsic functional connectivity from resting-state fMRI is an emerging Alzheimer's disease biomarker that holds promise for early diagnosis (Sperling et al., 2011; Badhwar et al., 2017). To analyze resting-state fMRI, select regions in canonical brain networks previously established in the literature are generally considered (1b). An individual resting-state fMRI connectivity map can be generated for different networks, with the default-mode, limbic, and salience networks being the key components affected by Alzheimer's disease (Badhwar et al., 2017) (1b). Structural and functional brain maps enter a subtyping procedure, which identifies groups of individuals with homogeneous brain maps (1c). The number of subtypes are defined a priori or through various metrics for model selection (Seghier, 2018) (for example N=3 in 1c). A subtype map is generated by averaging the maps within each subgroup and subtracting the grand average (i.e. demeaned) to emphasize the features of the subtype. Chi square statistics are applied to identify groups that include a greater number of Alzheimer's disease patients than expected by chance (illustrated by a “*AD” annotation for subtype 2 in 1c). In 1d, the subtyping procedure was applied on maps of grey matter density from CN and Alzheimer's disease dementia individuals in the ADNI database (N=377). Four out of seven subtypes were identified as Alzheimer's disease dementia-related (results adapted from Tam and colleagues (Tam et al., 2018)). Three subtypes were consistent with previous reports: posterior (or temporo-occipito-parietal-predominant), diffuse, and temporal (or medial temporal-predominant) atrophy subtypes. A novel language atrophy subtype was also identified. In 1e, the subtype procedure was applied to resting-state fMRI data collected on CN, MCI, and Alzheimer's disease dementia individuals in a dataset pooling ADNI2 with several independent samples (N=130). Three subtypes were extracted for three resting-state networks known to be impacted by Alzheimer's disease: default-mode, salience, and limbic. One Alzheimer's disease dementia/MCI-related subtype was found for each network. The salience and default-mode followed similar patterns: increased within-network connectivity, and a lower (negative) connectivity between networks. The limbic subtypes showed lower connectivity with frontal regions, and increased connectivity with occipital regions. Results adapted from Orban et al. (Orban et al., 2017). The section on “Brain Subtypes” compares results from the above-mentioned and other studies with similar approaches and objectives. Supplementary Table S1 provides detailed characteristics of the 12 neuroimaging subtyping studies (structural MRI and resting-state fMRI) that met our search criteria. Abbreviations: BOLD (blood oxygen level dependant signal)
**Anatomical subtypes**

The spatial distribution of brain atrophy on structural MRI is highly heterogeneous in MCI, and Alzheimer's disease dementia patients (Nettiksimmons et al., 2014; Poulakis et al., 2018). Using data-driven clustering algorithms, 11 studies have attempted to subtype and characterize this inherent heterogeneity (Supplementary Table S1). Seven studies reported at least three distinct atrophy subtypes in Alzheimer's disease dementia (Noh et al., 2014; Hwang et al., 2016; Park et al., 2017; Poulakis et al., 2018; ten Kate et al., 2018), or mixed (Alzheimer's disease dementia and CN) cohorts (Varol et al., 2017; Tam et al., 2018). Subtypes were generally consistent across studies, and can be described as diffuse, medial-temporal-predominant (temporal), and temporo-occipito-parietal-predominant (posterior) (Fig. 1d).

They were generated by applying (1) hierarchical agglomerative clustering using Ward’s clustering linkage (Noh et al., 2014; Hwang et al., 2016; Tam et al., 2018), Louvain clustering (Park et al., 2017), random forest clustering (Poulakis et al., 2018), or non-negative matrix factorization (ten Kate et al., 2018) on cortical thickness or grey matter density maps, or (2) clustering on grey matter density maps using a novel approach called HYDRA (Varol et al., 2017). Good agreement across studies may, in part, reflect usage of the same data sample (ADNI) for subtype identification in four studies (Hwang et al., 2016; Varol et al., 2017; Poulakis et al., 2018; Tam et al., 2018). Some studies report two-subtype decomposition (Dong et al., 2016; Malpas, 2016), but these lack inter-study consensus. Using model-based clustering on regional cortical thickness measures from ADNI, Malpas reported normal and atrophic-entorhinal subtypes in a sample including Alzheimer's disease dementia, and CN individuals (Malpas, 2016). The atrophic-entorhinal subtype demonstrated considerable heterogeneity in entorhinal thickness, suggesting the presence of additional subtypes (Malpas, 2016). Dong et al. reported limbic-insular, and parietal-occipital atrophy subtypes using CHIMERA clustering on brain volume data from Alzheimer's disease dementia and CN ADNI participants (Dong et al., 2016). In a separate study, the same group reported four atrophy subtypes using CHIMERA: normal, temporal, and two diffuse subtypes - one with predominant temporal involvement (diffuse-temporal), and one without (diffuse) (Dong et al., 2017). Visually, the diffuse subtype from CHIMERA shared some overlap with the posterior subtype described previously. In general, the reported subtypes (Dong et al., 2017) fit better with the three subtype solution, considering that, unlike previous studies, the CHIMERA study included CN individuals. Finally, Tam et al. identified a fourth atrophy subtype involving several language-related areas (Tam et al., 2018).
The choice of the number of subtypes is to some degree arbitrary. Two studies showed that their three subtypes could be decomposed into six (Noh et al., 2014), or more (Tam et al., 2018) homogeneous groups. Finally, an additional study looking at heterogeneity with a linear mixture model, instead of a discrete cluster analysis, showed that most individuals tend to express varying levels of multiple subtypes (Zhang et al., 2016). Continuous measures of subtype similarity are thus more advisable than discrete assignment (Zhang et al., 2016; Tam et al., 2018).

We now highlight various associations between Alzheimer's disease markers/risk-factors and the three atrophy subtypes consistently reported. In three studies, Alzheimer's disease dementia patients with the posterior subtype were reported to be the youngest, and had the earliest age-at-onset (Noh et al., 2014; Hwang et al., 2016; Park et al., 2017). They also demonstrated greater PET-detectable amyloidosis (Hwang et al., 2016), and pathological levels of CSF Aβ42 and tau (Noh et al., 2014; Varol et al., 2017; ten Kate et al., 2018). Differences across subtypes were reported with FDG-PET-detectable glucose hypometabolism (Hwang et al., 2016), and white matter hyperintensities (ten Kate et al., 2018). Subtype-specific associations with Alzheimer's disease-related genes were observed, specifically, APOE (Noh et al., 2014; Varol et al., 2017), CD2AP (CD2-associated protein) (Varol et al., 2017), SPON1 (Spondin-1) (Varol et al., 2017), LOC390956 or PPIAP59 (peptidyl-prolyl cis-trans isomerase A pseudogene) (Varol et al., 2017), though the association with APOE was not consistently found (Hwang et al., 2016). Associations of subtypes with cognition were observed for global (Varol et al., 2017; Tam et al., 2018) and domain-specific (e.g. episodic memory) (Noh et al., 2014; Park et al., 2017; Poulakis et al., 2018; ten Kate et al., 2018) measures, but not by all studies (Hwang et al., 2016). Associations between subtypes and sex were found to be significant in two (Noh et al., 2014; Varol et al., 2017) of four (Noh et al., 2014; Hwang et al., 2016; Varol et al., 2017; Tam et al., 2018) studies.

**Functional subtypes**

By coupling cluster analysis and resting-state functional MRI, a preprint report by Orban et al. (Orban et al., 2017) investigated connectivity subtypes in CN, MCI, and Alzheimer's disease dementia patients (Supplementary Table S1). They noted associations between functional connectivity subtypes and cognitive symptoms in the default-mode, limbic, and salience...
networks in MCI, and Alzheimer's disease dementia patients (Fig. 1e). Limbic subtypes were also associated with Alzheimer's disease biomarkers (CSF Aβ42 levels, APOE4 genotype) in an independent cohort at increased risk for familial Alzheimer's disease, suggesting that functional connectivity subtypes may be sensitive to the presence and progression of preclinical disease (Orban et al., 2017).

Summary

Our review found convergent evidence of distinct brain atrophy subtypes in Alzheimer's disease dementia patients, including at least three data-driven Alzheimer's disease atrophy subtypes: diffuse, temporal, and posterior. These structural subtypes seem to associate with established biomarkers, risk factors, and clinical symptoms of Alzheimer's disease, as well as cognitive subtypes: temporal subtype with memory impairment, and diffuse subtype with impaired executive function (Zhang et al., 2016). The picture emerging from fMRI data is one of aberrant between-network connectivity initiating in the mesolimbic network at the preclinical stage and propagating to the salience and default-mode network with Alzheimer's disease progression (Orban et al., 2017).
Metabolomics Panels

Figure 2: A typical Alzheimer's disease metabolomics biomarker discover pipeline

Metabolomics is a relatively recent addition to the systems biology toolkit for the study of NDDs of aging (Wilkins and Trushina, 2017). It encompasses the global study of small molecules (50-1500 daltons in mass), that are substrates and products of metabolism. Together, these metabolites (e.g. amino acids, antioxidants, vitamins) represent the overall physiological status of the organism. An individual’s metabolic activity is influenced by an individual’s genotype and environment (Kaddurah-Daouk et al., 2011). Analysis of the metabolome, therefore, provides an opportunity to study the dynamic molecular phenotype of an individual. Untargeted metabolomics approaches are increasingly used to compare two or more groups (e.g. Alzheimer's disease dementia and CN participants) and identify metabolite profiles associated with a disease. These profiles provide insight into underlying disease mechanisms, as well as constitute candidates for biomarker discovery and drug development. In the field of Alzheimer's disease research, metabolomics studies (targeted and untargeted) over the last decade have examined several biofluids and tissues, including serum, plasma, CSF, saliva, urine, and brain tissue (Wilkins and Trushina, 2017). Technologies include NMR (nuclear magnetic resonance) spectroscopy and mass spectrometry. In 2a, a typical Alzheimer's disease
metabolomics biomarker discovery pipeline using MS-LC (mass spectrometry-liquid chromatography) is depicted. Subsequent to metabolite extraction, identification, and quantification, most studies apply multivariate statistical methods to the metabolome data to identify the top discriminant metabolites. These can be further combined into metabolite-panels to increase discriminative power (i.e. sensitivity and specificity) in Alzheimer's disease prediction and progression (Liang et al., 2015, 2016; Huan et al., 2018). Significant discriminative power is commonly tested with the Receiver Operating Characteristic curve analysis (area under the curve or AUC values). Discriminant metabolite-panels are then validated in independent samples. Following discriminant metabolite(s) discovery, researchers conduct pathway and network analyses, which provide crucial mechanistic insights into the sequences of processes leading to the heterogeneous phenotypes of neurodegeneration. Pathway analysis focus on identifying sequences of processes that lead to the presence of a discriminant metabolite. Network analysis examine how discriminant metabolites are connected to each other within Alzheimer's disease and related dementias. In 2b, we show the three main metabolic pathways (namely, amino acid, lipid and nucleic acid) that 90 Alzheimer's disease-associated metabolites in our review (N=11 publications, Supplementary Table S2) were found to belong. The text color indicates the biofluid metabolome each metabolite was identified in: red = serum or plasma, purple = saliva, black = CSF. A larger font size indicates that the metabolite was identified in more than one study (see Supplementary Table S3 for details) The maximum number of studies a metabolite was detected in our review was four. * indicates that the metabolite was identified in more than one biofluid; ** indicates presence in plasma or serum and saliva, *** indicates presence in plasma or serum and CSF. Abbreviations: AD, Alzheimer’s disease; CN, cognitively normal; MCI, mild cognitive impairment.

**Metabolite Panels**

We reviewed six Alzheimer's disease studies that constructed metabolite panels from top discriminant metabolites in biofluids: 2 plasma, 1 serum, 2 saliva, and 1 CSF (Supplementary Table S2). Using plasma metabolome data, Wang et al. (Wang et al., 2014) constructed a six-metabolite panel to discriminate Alzheimer's disease dementia from CN, and a five-metabolite panel to discriminate amnestic MCI from CN. Arachidonic acid, N,N-dimethylglycine, and thymine were present in both panels. Association of panel metabolites with lipid, amino acid, or nucleic acid metabolism suggested specific metabolic deregulations in Alzheimer's disease. Mapstone et al. (Mapstone et al., 2017) used a 12-plasma-metabolite panel to discriminate the
following cohorts from CN: older adults with superior memory; amnestic MCI + Alzheimer's disease dementia patients; and participants who converted to amnestic MCI or Alzheimer's disease dementia in approximately two years. Similar to Wang et al. (Wang et al., 2014), several panel metabolites were associated with lipid or amino acid metabolism. Panel metabolites were also found to be constituents of pathways regulating oxidative stress, inflammation, and nitric oxide bioavailability. Using serum metabolome data, Liang et al. (Liang et al., 2016) identified a panel of two lipid metabolites (spinganine-1-phosphate, 7-ketocholesterol) that discriminated MCI from Alzheimer's disease dementia. Sphinganine-1-phosphate was also present in a three-metabolite panel constructed from the salivary metabolome, and discriminated Alzheimer's disease dementia patients from CN (Liang et al., 2015). The other two panel members, ornithine and phenyllactic acid, were amino acid metabolites (Ogata et al., 1999) with links to the same oxidative stress pathway reported by Mapstone et al. (Mapstone et al., 2017) A separate study using saliva reported a seven-metabolite panel that discriminated pre-dementia (i.e. five years prior to dementia onset) from CN (Figueira et al., 2016). Metabolites were associated with amino acid, lipid, or energy metabolism. Czech et al. (Czech et al., 2012) assessed multiple combinations of 16 CSF metabolites to discriminate Alzheimer's disease dementia from CN. Highest discrimination was obtained with a 5-metabolite panel consisting of cortisol and amino acids. Our focused review of Alzheimer's disease-associated metabolite panels highlight that the majority of discriminant molecules detected in biofluids are involved in amino acid, lipid, or nucleic acid metabolism (Fig. 2b).

**Metabolomics Pathways and Networks**

We reviewed five Alzheimer's disease studies that followed up non-targeted metabolomics research in biofluids with pathway or network analyses: 2 plasma, 1 plasma plus CSF, and 2 serum (Supplementary Table S2). In plasma, de Leeuw et al. (de Leeuw et al., 2017) identified 26 metabolites comprised of mainly amino acids and lipids with significantly altered levels in Alzheimer's disease dementia patients. Network analyses suggested a shift in Alzheimer's disease towards amine and oxidative stress compounds, known to cause imbalances in neurotransmitter production, Aβ generation, and neurovascular health. Perturbations in amino acid metabolism (interlinked polyamine and L-arginine pathways) was also demonstrated in the plasma metabolome of MCI to Alzheimer's disease dementia converters (Graham et al., 2015). Changes in polyamine and L-arginine metabolism have been linked to neurotoxicity, and deregulations in genesis and/or death of neural cells and neurotransmitter production
Other metabolic pathways notably impacted were cholesterol, glucose, and prostaglandin (Graham et al., 2015). Cholesterol metabolism (specifically cholesterol and sphingolipids transport) was also found to be abnormal in both plasma and CSF from Alzheimer's disease dementia patients (Trushina et al., 2013). In serum, metabolism of amino acids dominated the top pathways altered in Alzheimer's disease dementia patients in one study (González-Domínguez et al., 2015), a finding in line with plasma metabolome data (de Leeuw et al., 2017). A second study in serum reported a 3-metabolite panel predictive of progression from MCI to Alzheimer's disease dementia (within 27±18 months), with major contribution from up-regulated 2,4-dihydroxybutanoic acid, a metabolite potentially overproduced during hypoperfusion-related hypoxia (Orešič et al., 2011). Upregulation of the pentose phosphate pathway in progressors further supported the involvement of secondary hypoxia in Alzheimer's disease pathogenesis. More glucose is metabolized via the pentose phosphate pathway in the brain under hypoxic conditions.

**Summary**

Overall, metabolite panels, and metabolomics pathway and network analyses provide the following insights: (1) discriminant Alzheimer's disease-associated metabolites may be narrowly or broadly interconnected (Wilkins and Trushina, 2017); (2) metabolomes of different biofluids provide convergent and biofluid-related mechanistic insights into Alzheimer's disease pathology (Trushina et al., 2013); (3) genotype-associated (e.g. APOE status) differences in preclinical and clinical groups suggest different routes to Alzheimer's disease (de Leeuw et al., 2017), (4) neurodegenerative disease subtypes can be characterized by metabolomics analyses (de Leeuw et al., 2017).
Genomics-derived Polygenic Risk Scores

Figure 3: Polygenic Risk Scores

High-throughput genotyping technologies have revolutionized studies in diseases with complex genetics by enabling detection of common genetic variants with low effect sizes, and rarer variants with relatively higher effect sizes (see 3a). In Alzheimer's disease, the prevalent late-onset variant is genetically complex and demonstrates high heritability (up to 80%) (Gatz...
et al., 2006), whereas the early-onset familial variant is deterministically driven by single gene mutation(s) in PSEN1 (presenilin 1), PSEN2 (presenilin 2) or the APP (amyloid precursor protein) (Guerreiro et al., 2013). The genetics of late-onset Alzheimer's disease has been predominantly investigated using GWAS. Designed to rapidly scan for statistical links between a set of known SNPs and a phenotype of interest, GWAS can identify common variants with MAF greater than 5% (Torkamani et al., 2018) (see 3a). Up to 24 key Alzheimer's disease-risk genes have been identified using GWAS (Supplementary Table S4). Identification of rarer Alzheimer's disease-associated SNPs (MAF >0.5% and <5%), that often escape detection with GWAS, is being enabled by NGS technologies, such as whole-exome sequencing and targeted resequencing of disease-associated genes (Bras et al., 2012; Masellis et al., 2013) (see Supplementary Table S4 for examples). NGS technologies provide transcriptome-wide coverage without requiring any a priori knowledge of SNPs (3a). To date, Alzheimer's disease prediction using individual high-throughput genotyping technologies identified risk genes have been predominantly non-significant, with the exception of APOE, which accounts for up to 30% of the genetic risk (Daw et al., 2000). Therefore, the search for risk genes beyond APOE now include polygenic risk score (PRS, also referred to as genetic risk scores, risk indexes or scales) approaches (3b). A PRS is a calculation (e.g. weighted sum) based on the number of risk alleles carried by an individual, where the risk alleles and their weights are defined by GWAS-detected loci and their measured effects (Torkamani et al., 2018). In the most common scenario, only SNPs reaching conventional GWAS significance ($p < 5 \times 10^{-8}$) are included (3c). A threshold lower than the genome-wide statistical significance (e.g. $p = 10^{-5}$) can also be used to improve or estimate total predictability (Torkamani et al., 2018) (3c). SNPs representing multiple hits among Alzheimer's disease risk genes from one or more major mechanistic pathways can also be included into a PRS (3c). Displayed are six main mechanistic clusters, each populated by genetic variants thought to represent the cluster (3d). Genetic variants have been placed within the cluster according to population frequency (horizontal axis) and level of estimated risk (vertical axis). For example, an Aβ/APP metabolism cluster is made up of rare ADAM10 (a disintegrin and metalloproteinase domain-containing protein 10) and common APOE4+ higher risk genes, and rare PLD3 (phospholipase D family member 3) and common PICALM (phosphatidylinositol binding clathrin assembly protein) lower risk genes. Some genes are involved with multiple mechanisms as can be seen for PICALM’s involvement in nervous function, basic cellular processes, and Aβ/APP metabolism. As implied in the figure, when creating PRS, it may be very useful to select genes within mechanistic groups, and select
groups depending on the purpose of the research. In sum, PRS reflect a large number of SNPs and a complex set of biological mechanisms related to Alzheimer's disease pathogenesis, and can improve the precision of early Alzheimer's disease risk or diagnosis (Desikan et al., 2017; Escott-Price et al., 2017; Morgan et al., 2017).

**Polygenic Risk Score Approach or PRS**

Constructed of multiple SNPs that implicate one or more biological mechanisms, PRS (Fig. 3) are better at discriminating Alzheimer's disease from CN than single-gene analysis (Escott-Price et al., 2017; Torkamani et al., 2018). We reviewed 11 Alzheimer's disease PRS studies (Supplementary Table S4, S5), the majority comprised of GWAS-detected SNPs. To identify genetic risk beyond that of APOE alone, several studies assessed PRS with (APOE-PRS) and without (non-APOE-PRS) APOE. Desikan et al. (Desikan et al., 2017) found that an APOE-PRS associated with age-at-onset of Alzheimer's disease symptoms, decreased Aβ and increased tau in CSF, and increased atrophy, tau, and Aβ load in brain. APOE-PRS also associated with plasma inflammatory markers in Alzheimer's disease patients (Morgan et al., 2017). An APOE-PRS including a rare TREM2 (triggering receptor expressed on myeloid cells 2) variant discriminated Alzheimer's disease dementia and CN, with increasing scores associating with decreasing age-at-onset, and CSF Aβ42 (Sleegers et al., 2015). Discriminative power of APOE-PRS was found to improve with diagnostic accuracy, as demonstrated using a pathologically confirmed Alzheimer's disease cohort (Escott-Price V, Myers, AJ, Huentelman M, Hardy, J, 2017). In four separate studies, a non-APOE-PRS was reported to discriminate between Alzheimer's disease dementia and CN (Xiao et al., 2015), as well as associate with MCI (Adams et al., 2015), increased risk of Alzheimer's disease dementia (Adams et al., 2015; Chouraki et al., 2016; Tosto et al., 2017), and earlier Alzheimer's disease onset (Tosto et al., 2017). Inclusion of APOE either resulted in a modest increase in discriminative power (Xiao et al., 2015), stronger clinical or biomarker associations (Adams et al., 2015; Chouraki et al., 2016), or had no additional effect (Tosto et al., 2017). In another non-APOE-PRS study in Alzheimer's disease patients, PRS scores correlated negatively with CSF Aβ42 levels, and positively with temporal cortex Aβ pathology, and γ-secretase activity (Martiskainen et al., 2015). Naj et al. (Naj et al., 2014) found that though APOE contributed to 3.7% of age-at-onset variability in Alzheimer's disease dementia patients, adding a non-APOE-PRS accounted for an additional 2.2%. Overall, Alzheimer's disease heritability has a large polygenic contribution.
beyond \textit{APOE}, which makes PRS approaches pivotal for Alzheimer's disease-risk prediction (Escott-Price \textit{et al.}, 2015).

\textbf{Mechanism-based Interaction and Network Approaches}

Alzheimer's disease-risk genes can be clustered into functional/mechanistic pathways (Fig. 3d), and the information gained utilised to improve Alzheimer's disease discrimination and/or risk prediction (Gaiteri \textit{et al.}, 2016; Hu \textit{et al.}, 2017). We reviewed six mechanism-based Alzheimer's disease studies (Supplementary Table S5). Functional variants of Alzheimer's disease GWAS-significant SNPs (e.g. \textit{CELF1} or \textit{CUGBP Elav-like family member 1}) was reported to associate with human brain expression quantitative trait loci, and preferentially expressed in specific cell-types (e.g. microglia) (Karch \textit{et al.}, 2016). Rosenthal \textit{et al.} (Rosenthal \textit{et al.}, 2014) highlighted the potential regulatory functions of non-coding Alzheimer's disease GWAS SNPs. Protein-protein interaction network analyses highlighted that Alzheimer's disease-risk genes whose protein-products interact physically may be under positive evolutionary selection (e.g. \textit{PICALM} or \textit{phosphatidylinositol binding clathrin assembly protein}, \textit{BIN1} or \textit{bridging integrator 1}, \textit{CD2AP} or \textit{CD2 associated protein}, \textit{EPHA1} or \textit{EPH receptor A1}) (Raj \textit{et al.}, 2012). Ebbert \textit{et al.} (Ebbert \textit{et al.}, 2014) reported that while an \textit{APOE}-PRS did not improve discrimination of Alzheimer's disease from CN over \textit{APOE}, a model allowing for epistatic interactions between SNPs increased discriminative power. Patel \textit{et al.} (Patel \textit{et al.}, 2016) applied a stratified false discovery rate approach, used to increase GWAS power by adjusting significance levels to the amount of overall signal present in data, to identify gene networks and provide links with sMRI phenotypes: e.g. linking genes involved in transport (e.g. \textit{SLC4A10} or \textit{solute carrier family 4 member 10}, \textit{KCNH7} or \textit{potassium voltage-gated channel subfamily H member 7}) with hippocampal volume. Huang \textit{et al.} (Huang \textit{et al.}, 2018) integrated Alzheimer's disease GWAS genes with human brain-specific gene network using machine learning to identify additional Alzheimer's disease-risk genes.

\textbf{Summary}

In sum, PRSs may contribute substantially to accounting for the genetic variability that distinguishes Alzheimer's disease from MCI and CN groups. They may also be used to probe genetic underpinnings of Alzheimer's disease subtypes as well as related and disparate NDDs. Thus far, research reporting PRSs in relation to conversion rates of CN or MCI to Alzheimer's disease dementia have been mixed (Adams \textit{et al.}, 2015; Lacour \textit{et al.}, 2017), but early PRS
prediction of cognitive trajectories and clinical outcomes have also been reported (Sapkota and Dixon, 2018).

Discussion

Roadmap for assembling multiomics measures into diagnostic tool

On the complementarity of multiomics biomarkers

Individuals clinically diagnosed with an NDD of aging (e.g. Alzheimer's disease) exhibit varying loads of neurodegenerative markers (e.g. Aβ, tau, alpha-synuclein, brain atrophy, vascular abnormalities) (Beach et al., 2012; Robinson et al., 2018). Single-domain omics biomarkers can, to an extent, characterize this heterogeneity \textit{in vivo}. Some data-driven brain atrophy subtypes parallel established clinical diagnoses. For example, the posterior atrophy subtype is evocative of the PCA Alzheimer's disease variant, and the language atrophy subtype of the lvPPA variant (Ossenkoppele et al., 2015). An active area of research is to determine to what degree the “bottom-up”, fully automated and data-driven subtypes match with established “top-down” clinical assessments, which usually start with cognitive symptoms and then incorporate specific neuroimaging characteristics, such as left temporoparietal atrophy in lvPPA (Ossenkoppele et al., 2015). The fact that reviewed studies included participants with typical late-onset Alzheimer's disease dementia, and not atypical variants such as PCA, suggest that specific brain atrophy phenotypes comprise a spectrum of involvement that may overlap a clinical label, but not associate uniquely with one. It is unclear how functional connectivity subtypes tie in with atrophy subtypes, although they both associate with clinical diagnoses and biomarkers and risk factors of Alzheimer's disease (Zhang et al., 2016; Orban et al., 2017). Although the propagation of functional dysconnectivity parallels the Braak staging of Alzheimer's disease, the mix of connectivity increases and decreases observed in patients may reflect transient compensatory mechanisms as well as neurodegeneration (Badhwar et al., 2017). To date, we are unaware of studies that have associated data-driven Alzheimer's disease brain subtypes with PRS and/or metabolite panels, but our review strongly supports such coordinated multiomics approaches. For example, an Alzheimer's disease PRS comprised of genes linked to lipid metabolism and inflammatory response may associate with panels comprised of metabolites involved in corresponding pathways. One could further speculate whether the resulting inflammation may cause the diffuse atrophy subtype, and trigger specific
functional compensatory mechanisms. Testing these hypotheses will require a cohort that is both deeply phenotyped and captures the entire spectrum of age-related dementia.

A roadmap for parsing heterogeneity in neurodegeneration

A data-driven characterization of heterogeneity across the NDDs of aging will require cohorts representative of the spectrum of neurodegeneration. The cohort assembled by the Canadian Consortium on Neurodegeneration in Aging (CCNA, http://ccna-ccnv.ca/) provides a new opportunity to study the full spectrum of age-related dementia. By 2019, the cohort will include 2,310 individuals (ages 50-90) featuring the following cognitive conditions: Alzheimer's disease, vascular, Lewy Body, Parkinson's, frontotemporal, and mixed etiology dementias, as well as subjective cognitive impairment, MCI, vascular MCI, and CN (Fig. 4).
Figure 4: proposed roadmap to discovering multiomics Alzheimer's disease biomarkers

Panel 1 (COMPASS-ND): The COMPASS-ND cohort is comprised of people with various types of dementia or cognitive complaints, as well as healthy, cognitively normal individuals. 

Panel 2 (Omics data): Performing dimension reduction for omics data. Featured as examples are some of the results of our review of the Alzheimer's disease literature as presented earlier in the paper. 

Panels 3–5 (Machine Learning, Multiomics Biotypes and Prediction): demonstrate how signatures of neurodegeneration derived from the integration of multiomics data using
machine learning techniques will better identify individuals on an Alzheimer's disease spectrum trajectory. While our proposed roadmap addresses multiomics biomarkers for Alzheimer's disease, a similar approach can be used for other neurodegenerative diseases of aging. Abbreviations: Alzheimer’s Disease (AD), FrontoTemporal Dementia (FTD), Lewy Body Disease (LBD), Vascular Cognitive Impairment (VCI), Mixed etiology dementia (Mixed), Cognitively normal (CN), Subjective Cognitive Impairment (SCI), Mild Cognitive Impairment (MCI), Imaging features (I), Metabolic features (M), Genomics features (G), clinical and demographic features (O).

The cohort composition ensures that age-related dementias are more or less equally represented, even for less prevalent dementia types (e.g. frontotemporal dementia). Participants will be deeply phenotyped with extensive clinical, neuropsychological, neuroimaging, biospecimen, and neuropathological assessments.

In Fig. 4 we present a roadmap for a multiomics approach to heterogeneity in NDD. We begin with a heterogeneous clinical cohort design that enables the discovery of subgroups sharing a common signature across multiple omics domains (biotypes) that are highly predictive of the clinical status and evolution of individual patients. Multiomics biotypes will be complemented by other important variables such as sex, presence of Aβ and tau deposits, and vascular abnormalities. Machine learning tools will be applied to identify an optimal combination of different biotypes and explanatory variables that either discriminate different clinical cohorts, or are predictive of future progression of specific symptoms (Fig. 4).

Towards highly predictive multiomics signatures

Biomarkers of Alzheimer's disease dementia demonstrate limited predictive power in the prodromal phase (Rathore et al., 2017). For example, Korolev et al. (Korolev et al., 2016) reached about 80% accuracy (specificity 76%, sensitivity 83%) by including cognitive, multimodal imaging, and plasma-proteomics measures in a predictive model of progression. The best models include a combination of cognitive, sMRI, FDG-PET, and/or amyloid-PET measures (Rathore et al., 2017). A substantial proportion of patients identified as progressors, even by the best model, will remain stable over time. Given a 30% baseline rate of progressors in an MCI cohort, and a prediction achieving a sensitivity and specificity of 80%, 37% of patients identified as progressors by the model will remain stable. This limited positive predictive value is likely explained by sample heterogeneity. For example, Dong et al. (Dong...
Badhwar et al., 2017) reported two atrophy subtypes with higher-than-expected rates of progression to dementia, but one subtype was much more at risk than the other. Thus, an important first step to precision medicine is to identify specific subsets of patients where an accurate prediction can be made.

Multiomics signatures can be used to improve the accuracy of early prognosis, but they also capture a range of information, ranging from brain networks targeted by the disease, metabolic abnormalities in specific pathways, and distinct genetic backgrounds. The multiomics signature thus may also help elucidate the specific pathophysiological pathways involved. Overall, multiomics biomarkers have the potential to reshape clinical diagnosis, and define new “bottom up” cohorts based on markers of underlying pathologies to design and evaluate drugs.

Author Contributions

AB, PB, RAD, GPM, and SS designed and wrote the manuscript. AB, GPM and SS performed literature search and compiled tables. AB, PB, RAD, GPM and SS made the figures and MM provided input. MM, LL, SD, HC, and SEB helped with the writing and interpretation of specific sections of the manuscript.

Acknowledgements

We would like to thank Dr. Sridar Narayanan for helpful comments on the manuscript.

Funding

This review was performed by members of the Biomarkers Team of the Canadian Consortium on Neurodegeneration in Aging (CCNA; Team Leads: RAD and PB) which is funded by the Canadian Institutes of Health Research (CIHR) and partners. Additional sources of support are as follows. AB is currently supported by a CIHR Postdoctoral Fellowship (funding reference number #152548) and the Courtois Foundation. At the start of the project AB was supported by the Alzheimer Society of Canada Postdoctoral Fellowship. PB is a Research Scholar from the Fonds de recherche du Québec, and is also supported by the Courtois Foundation. SS is supported by the Alzheimer Society of Canada Postdoctoral Fellowship. RAD and GPM are also supported by the U.S. National Institutes of Health (National Institute on Aging, R01 AG008235). SD is a Research Scholar from the Fonds de recherche du Québec – Santé [grant number 30801]. The Consortium d’identification précoce de la maladie d’Alzheimer – Québec
is financed through the Fonds de recherche du Québec – Santé / Pfizer Canada Innovation Fund [grant number 25262].

Competing Interests
The authors report no conflict of interest with regards to submitted manuscript.

Supplementary Material
We have provided 5 tables in supplementary material: Supplementary Tables S1, S2, S3, S4, and S5.
