Amyloid-β CSF/PET discordance vs tau load 5 years later:
It takes two to tangle

Abstract

OBJECTIVE: To investigate the association between discordant amyloid-β PET and CSF biomarkers at baseline and the emergence of tau pathology 5 years later.

METHODS: We included 730 ADNI participants without dementia (282 cognitively normal, 448 mild cognitive impairment) with baseline [18F]Florbetapir PET and CSF Aβ42 available. Amyloid-β CSF/PET status was determined at baseline using established cut-offs. Longitudinal data was available for [18F]florbetapir (Aβ) PET (baseline to 4.3±1.9 years), CSF (p)tau (baseline to 2.0±0.1 years), cognition (baseline to 4.3±2.0 years), and [18F]flortaucipir (tau) PET (measured 5.2±1.2 years after baseline to 1.6±0.7 years later). We used linear mixed modelling to study the association between amyloid-β CSF/PET status and tau pathology measured in CSF or using PET. Additionally, we calculated the proportion of CSF+/PET- participants who during follow-up (i) progressed to amyloid-β CSF+/PET+, and/or (ii) became tau-positive based on [18F]flortaucipir PET.

RESULTS: Amyloid-β CSF+/PET+ (N=318) participants had elevated CSF (p)tau levels and worse cognitive performance at baseline, while CSF+/PET- (N=80) participants were overall similar to the CSF-/PET- (N=306) group. Five years after baseline, [18F]flortaucipir PET uptake in the CSF+/PET- group (1.20±0.13) did not differ from CSF-/PET- (1.18±0.08, p=0.69), but was substantially lower than CSF+/PET+ (1.48±0.44, p<0.001). Of the CSF+/PET- subjects, 21/64 (33%) progressed to amyloid-β CSF+/PET+, whereas only one (3%, difference p<0.05) became tau-positive based on [18F]flortaucipir PET.

CONCLUSIONS: Sufficient amyloid-β load detectable by both CSF and PET is required before substantial tau deposition emerges. Compared to participants with abnormal amyloid-β levels on PET and CSF, the CSF+/PET- group has a distinctly better prognosis.
Introduction

Amyloid-β plaques and neurofibrillary tau tangles are considered the pathological hallmarks of Alzheimer’s disease (AD). Amyloid-β pathology can be measured in vivo directly by quantifying the fibrillary depositions using positron emission tomography (PET), or indirectly by detecting the decrease of soluble Aβ42 in cerebrospinal fluid (CSF). Although these two measures are sometimes considered interchangeable, 10-20% cases show discordant results, especially at earlier stages of AD. Therefore, it has been proposed that decreased Aβ42 in CSF without significant tracer uptake on PET (i.e. amyloid-β CSF+/PET-) marks the pathological beginnings of amyloid-β accumulation. This provides a powerful model to study the dynamic changes in amyloid-β as well as tau pathology during the earliest stages in the disease course of AD. Although CSF tau biomarkers have been available for over two decades, tau PET using radiotracers such as [18F]flortaucipir has only more recently been developed. Tau PET offers the unique opportunity to study the spatial distribution of tau aggregates in vivo.

An open question to date is whether isolated amyloid-β positivity in CSF is followed by significant tau deposition already at this stage, or whether it will be subsequent to more advanced amyloid-β pathology detectable by both modalities (i.e. CSF and PET). As tau has a stronger correlation to neurodegeneration and cognitive function than amyloid-β accumulation, this is of high clinical relevance. Furthermore, a better understanding of the interplay between the AD hallmark pathologies in early disease stages is crucial for the timing of interventions, as emerging treatments will likely be most effective when substantial neurodegeneration has not yet developed.

Methods

Participants

Data for this study was downloaded from the Alzheimer’s Disease Neuroimaging Initiative (ADNI) website, which also includes information about ADNI inclusion criteria and the procedure of biomarker acquisition. We selected all ADNI participants, who had at least one [18F]florbetapir amyloid-β PET scan and a CSF Aβ42 analysis available within one year. The diagnosis closest to baseline [18F]florbetapir PET within one year was used as the baseline diagnosis. In total, we included 730 pre-dementia subjects, of
whom 282 were cognitively normal (CN) and 448 had mild cognitive impairment (MCI) at baseline.

We used Mini-Mental State Examination (MMSE) to assess global cognition and composite z-scores to assess memory\textsuperscript{17} and executive functioning.\textsuperscript{18} Longitudinal cognitive assessment was available for 711 (97\%) subjects, with a median follow-up time of 4.2 [interquartile range (IQR): 2.9, 5.9] years. Similarly, a follow-up diagnosis was available for 724 (99\%) participants with a median interval between baseline and follow-up of 4.1 [IQR: 2.2, 5.9] years.

\textit{Standard protocol approvals, registrations, and patient consents}

Written informed consent was obtained for all participants, and study procedures were approved by the institutional re-view board at each of the participating centers. ADNI is listed in the ClinicalTrials.gov registry (ADNI-1: NCT00106899; ADNI-GO: NCT01078636; ADNI-2: NCT0123197).

\textit{[\textsuperscript{18}F]}florbetapir positron emission tomography

Acquisition and processing of \textit{[\textsuperscript{18}F]}Florbetapir PET using Freesurfer was performed as described previously.\textsuperscript{19,20} At least one follow-up PET scan was available for 579 (79\%) of participants with a median follow-up time of 4.1 [IQR: 2.1, 5.9] years. We used a neocortical composite score provided by ADNI consisting of the mean uptake in the frontal, cingulate, parietal and temporal regions. We created standardized uptake value ratios (SUVR) using whole cerebellum as the reference region and used an SUVR cut-off of 1.11 to determine binarized amyloid-\(\beta\) status based on PET.\textsuperscript{21,22} For longitudinal linear mixed modelling, we additionally used SUVR values in 34 regions from the Desikan-Killiany atlas using (i) the whole cerebellum,\textsuperscript{23} and (ii) a composite white matter region as reference regions, because the latter has been shown to be more reliable in longitudinal analyses.\textsuperscript{24} Finally, we used an early composite region identified in a recent study\textsuperscript{25} (including bilateral precuneus, posterior cingulate, insula, and medial and lateral orbitofrontal regions) to capture the early accumulation of amyloid-\(\beta\).

\textit{Cerebrospinal fluid}
Lumbar punctures were performed as previously described.\textsuperscript{26} CSF samples were frozen on dry ice after collection and transported to the UPenn Medical Center ADNI Biomarker Core laboratory. Thereafter, 0.5mL aliquots were prepared and stored in polypropylene tubes at -80°C. CSF samples were analyzed for Aβ\textsubscript{42}, total tau (t-tau) and phosphorylated tau (p-tau) using the AlzBio3 assays (Fujirebio) on the xMAP platform (Luminex). In case samples were reanalyzed, we used the median value of those results. A cutoff of 192 pg/mL was used to determine amyloid-β status based on CSF.\textsuperscript{26,27} Longitudinal CSF analyses were available for 297 (41%) of participants with the median follow-up time of 2.0 [IQR: 2.0, 2.0] years.

\textit{\textsuperscript{[18}F\textsuperscript{}]flortaucipir positron emission tomography}

\textsuperscript{[18}F\textsuperscript{}]Flortaucipir PET was performed at each ADNI site according to standardized protocols. Images were acquired via 4x5 minute frames from 80 to 100 minutes after injecting ~370 MBq of \textsuperscript{[18}F\textsuperscript{}]flortaucipir. \textsuperscript{[18}F\textsuperscript{}]flortaucipir PET was available for 253 (35%) participants and was performed a median of 5.2 [IQR: 4.2, 6.1] years after baseline \textsuperscript{[18}F\textsuperscript{}]florbetapir PET, allowing measuring tau pathology at a significantly later time-point. Of these participants, 110 had one follow-up scan after 1.3 [IQR: 1.0, 2.1] years. We used Freesurfer-defined Desikan-Killiany atlas regions provided by ADNI that were created by co-registering the \textsuperscript{[18}F\textsuperscript{}]flortaucipir image with a previously parcellated and segmented magnetic resonance imaging MPRAGE from the same time.\textsuperscript{28} Thereafter, we created three bilaterally volume-weighted composite regions to cover the full spectrum of tau aggregation: entorhinal cortex, temporal meta-ROI reflecting Braak stage I to IV (including entorhinal, parahippocampal cortex, amygdala, fusiform, inferior and middle temporal cortices), and Braak stage V and VI (including wider neocortical areas).\textsuperscript{29–31} Cut-offs (1.39, 1.34, and 1.28 SUVR, respectively) obtained using a similar PET pipeline were used to determine \textsuperscript{[18}F\textsuperscript{}]flortaucipir positivity.\textsuperscript{32}

\textit{Statistical analysis}

We selected the first available \textsuperscript{[18}F\textsuperscript{}]florbetapir PET as baseline amyloid-β PET, and CSF Aβ\textsubscript{42} closest in time within one year to the \textsuperscript{[18}F\textsuperscript{}]florbetapir PET as baseline CSF. Thereafter, we created four groups based on the binarized amyloid-β status on PET and CSF: concordantly amyloid-negative (CSF-/PET-), concordantly amyloid-positive (CSF+/PET+), discordantly amyloid-positive based on CSF (CSF+/PET-) or PET (CSF-/PET+). Participant groups were
compared using Chi-squared tests, two samples t-tests and Wilcoxon Rank-Sum tests. Statistical analysis was performed using R software version 3.5.3.33–36

We used linear mixed modelling to investigate longitudinal changes for (i) regional amyloid-β burden assessed by [18F]florbetapir PET, (ii) tau pathology assessed by CSF t-tau, p-tau (measured from baseline) and [18F]flortaucipir PET (measured 5 years after baseline), and (iii) cognitive measures (MMSE, and ADNI memory and executive composite scores). The models included time in years as a continuous variable, amyloid-β CSF/PET group, and an interaction between time*CSF/PET group. All models also included terms for age and sex. The models predicting regional amyloid-β PET and tau pathology based on CSF or PET were additionally adjusted for MMSE to account for clinical disease severity. The models predicting cognitive test results were additionally adjusted for education. We used a random intercept and a random slope for all models. We first selected CSF-/PET- as the reference group and interpreted the main effect of CSF/PET group status (CSF-/PET+ and CSF+/PET-) in the models as difference at baseline, and the CSF/PET group*time interaction term as the change over time. Thereafter, we repeated this analysis with CSF+/PET+ as the reference group. We then performed Kaplan-Meier survival analyses to investigate the association between amyloid-β CSF/PET status and clinical progression by using both overall progression (CN to MCI or dementia, or MCI to dementia) and progression to dementia (CN or MCI to dementia) as events. We additionally used Cox Regression analyses to obtain post hoc Hazard Ratios for each of the amyloid-β CSF/PET profiles.

Finally, we performed two analyses in CSF+/PET- participants only. First, to investigate subthreshold levels of tau pathology in the amyloid-β CSF+/PET- group, we performed linear regression models with amyloid-β pathology measured by [18F]florbetapir PET (globally as well as in early accumulating regions25) at baseline as the outcome, and cross-sectional tau pathology measured by either CSF t-tau or p-tau at baseline, or the three composite regions of [18F]flortaucipir PET five years later as predictors. Secondly, we investigated our hypothesis that progression from amyloid-β CSF+/PET- to CSF+/PET+ occurs at a higher rate than progression to tau-positivity based on [18F]flortaucipir PET. We calculated the proportions of CSF+/PET- participants, who (i) during the follow-up period converted into the CSF+/PET+ group based on the last available [18F]florbetapir PET scan and CSF analysis, and (ii) whose last available [18F]flortaucipir PET was positive in any of the 3 composite regions. We compared these outcomes by testing for overlapping 95% confidence intervals on estimated
proportions. Last available [\(^{18}\)F]flortaucipir PET was performed a median of 6.0 [IQR: 5.5, 6.8] years after baseline and 0.0 [-2.0, 1.4] years from last available [\(^{18}\)F]florbetapir PET.

Data availability

All imaging, demographics, and neuropsychological data used in this article are publicly available and were downloaded from the ADNI website (www.adni.loni.usc.edu). Upon request, we will provide a list of ADNI participant identifications for replication purposes.

Results

Study participants

Of the study participants, 306 (42%) were CSF-/PET-, 80 (11%) CSF+/PET-, 26 (4%) CSF-/PET+ and 318 (44%) CSF+/PET+ (Table 1). Characteristics were overall similar between CSF-/PET- and the two discordant groups. Participants in the CSF+/PET+ group had a higher proportion of APOE \(\varepsilon4\) carriers, were more often diagnosed with MCI, had lower cognitive scores, higher CSF (p)tau levels at baseline and higher [\(^{18}\)F]flortaucipir PET uptake five years later.

Accumulation of amyloid-\(\beta\)

First, we assessed regional [\(^{18}\)F]florbetapir patterns across groups (Figure 1, eTable 1 in the Supplement). Although the CSF-/PET+ group had more tracer uptake at baseline than CSF-/PET-, they did not accumulate significantly more amyloid-\(\beta\) over time on PET. Over time, CSF+/PET- group had widespread increase of tracer uptake compared to CSF-/PET- irrespective of the reference region. Additionally, CSF+/PET- had slightly more tracer uptake at baseline than CSF-/PET-.

Longitudinal trajectories of tau and cognition
Next, we investigated longitudinal trajectories of tau pathology (CSF and PET) and cognition (Figure 2, eTable 2 in the Supplement). Compared to amyloid-β CSF+/PET+ group, participants with discordant CSF/PET amyloid-β status had at baseline significantly (i) lower levels of CSF t-tau and p-tau measures (both p<0.001), (ii) less [18F]flortaucipir uptake in entorhinal cortex (both p<0.001), temporal meta-ROI (p<0.001 for CSF+/PET-, p=0.006 for CSF-/PET+) and Braak V/VI (p=0.002 for CSF+/PET-, p=0.274 for CSF-/PET+), and (iii) better cognitive test scores (MMSE: p=0.001 for CSF+/PET-, p=0.201 for CSF-/PET+; memory: both p<0.001; executive functioning: p=0.010 for CSF+/PET-, p<0.001 for CSF-/PET+). Longitudinally, participants in both CSF/PET discordant groups had lower rates of increase in [18F]flortaucipir uptake in temporal meta-ROI (p=0.010 for CSF+/PET-, p=0.031 for CSF-/PET+) and Braak V/VI composite areas (p=0.022 for CSF+/PET-), and less decline in cognitive test scores (all p<0.001 for both), compared to the CSF+/PET+ group. CSF+/PET-participants additionally had at baseline worse executive functioning than participants in the CSF-/PET- group (p=0.034). The CSF/PET discordant groups were otherwise similar to CSF-/PET-.

Clinical Progression

Next, we investigated the association between amyloid-β CSF/PET status and clinical progression using Kaplan-Meier estimates and Cox regression analyses (Figure 3, eTable 3 in the Supplement). Progression to either MCI or dementia occurred less often in amyloid-β CSF+/PET- (14%, hazard ratio [HR]= 0.22 [0.12, 0.41], p<0.001), CSF-/PET+ (8%, HR= 0.10 [0.02, 0.41], p=0.001) and CSF-/PET- (10%, HR= 0.16 [0.11, 0.24], p<0.001) participants, compared to the CSF+/PET+ (44%) group. Similarly, progression to dementia was rare in CSF+/PET- (5%, HR= 0.09 [0.03, 0.25], p<0.001) and CSF-/PET- (6%, HR= 0.11 [0.06, 0.17], p<0.001), but occurred more frequently in CSF+/PET+ (38%). No participants with amyloid-β CSF-/PET+ progressed to dementia.

Associations between amyloid-β and tau in CSF+/PET- participants

We then assessed whether continuous [18F]florbetapir uptake in the subthreshold range is correlated with tau measures in the amyloid-β CSF+/PET- group (Figure 4). [18F]florbetapir tracer uptake globally and in early accumulating regions was associated with higher baseline
CSF t-tau (p=0.001 and p=0.003), and higher [¹⁸F]flortaucipir uptake in entorhinal cortex (p=0.003 and p=0.010) and marginally in the temporal meta-ROI (p=0.062 and p=0.091).

Accumulation of amyloid-β and tau in CSF+/PET- participants

Finally, we investigated whether CSF+/PET- participants progress to CSF+/PET+ or become tau-positive first. Based on the last available [¹⁸F]florbetapir amyloid-β PET scan and CSF Aβ42 analysis, 21/64 (33%) of the baseline amyloid-β CSF+/PET- participants progressed to CSF+/PET+. Of 34 CSF+/PET- participants with [¹⁸F]flortaucipir PET available, 11/34 (32% [95% confidence interval: 17%, 48%]) progressed to CSF+/PET+, but only one (3% [95% confidence interval: -3%, 9%], difference in proportions p<0.05) turned tau-positive based on entorhinal or temporal meta-ROI regions, and none in Braak V/VI. For comparison, 2/123 (2%, p=1.00) of amyloid-β CSF-/PET-, 0/16 (0%, p=1.00) CSF-/PET+, and 47/80 CSF+/PET+ (59%, p<0.001) were tau-positive based on last available [¹⁸F]flortaucipir PET.

Discussion

We investigated the association between discordant CSF/PET amyloid-β biomarkers on tau pathology and clinical progression. Our main finding was that although amyloid-β CSF+/PET- participants showed longitudinal accumulation of amyloid-β based on PET, they had significantly less tau pathology based on both CSF at baseline and [¹⁸F]flortaucipir 5 years later compared to participants with CSF+/PET+ amyloid-β status. Similarly, discordant amyloid-β status was associated with better cognitive outcome and a lower risk of clinical progression than CSF+/PET+. We also showed that during follow-up, CSF+/PET- subjects frequently progressed to amyloid-β CSF+/PET+, whereas only one participant reached the threshold of tau-positivity based on [¹⁸F]flortaucipir PET. Finally, we showed a correlation between tau measures and global amyloid-β PET tracer uptake, indicating possible subthreshold accumulation of AD pathology in CSF+/PET- subjects. Taken together, our findings suggest that CSF+/PET- amyloid-β status is associated with a distinctly better prognosis than CSF+/PET+, and that a sufficient amyloid-β load detectable by both CSF and PET is required before significant tau deposition emerges.

Using both CSF tau measures and [¹⁸F]flortaucipir PET we found that participants with discordant CSF/PET amyloid-β status had less tau pathology than CSF+/PET+ amyloid-β, and
comparable tau load as observed in concordant amyloid-β negative participants. It has been proposed that CSF+/PET- status can be caused by CSF Aβ42 being able to detect amyloid-β at an earlier stage due to the decrease of soluble Aβ42 in CSF preceding fibrillary depositions visualized by PET. This is supported by higher rates of CSF+/PET- compared to CSF-/PET+ across several studies.7,37,38 Previous longitudinal PET studies have shown that subjects with CSF+/PET- amyloid-β status show significant accumulation of amyloid-β over time.8,9,39 We replicated this finding in our study, further supporting the notion that CSF+/PET- amyloid-β status identifies the beginnings of amyloid-β accumulation. Although participants with CSF-/PET+ amyloid-β status had higher [18F]florbetapir tracer uptake at baseline, they did not show significant accumulation of amyloid-β over time. Combined with the lack of clinical progression in this group, these observations suggest that isolated amyloid-β PET positivity might be caused by non-specific tracer uptake in the white matter, processing errors or other unknown factors.6 In CSF+/PET- participants, the lack of substantial tau pathology based on CSF tau measures at baseline and on [18F]flortaucipir PET five years later, accompanied by lack of cognitive decline and clinical progression, suggests these subjects have a distinctly more favorable prognosis than subjects with CSF+/PET+. This is likely caused by the remarkably slow course of AD, which is characterized by gradual accumulation of pathology over time.40,41 Accounting for the more benign prognosis of CSF+/PET- subjects is important for the timing of future interventions at the earliest stages of AD pathology.

Current hypothetical biomarker models suggest that accumulation of amyloid-β pathology is followed by detectable cortical tau pathology, subsequently leading to neurodegeneration and cognitive decline.42,43 Although it has been proposed that CSF+/PET- is followed by conversion to CSF+/PET+,8,44 the exact timing of CSF+/PET- status in regard to that timeline, in particular towards accumulation of tau, is unknown. We found that within five years, one third of the CSF+/PET- participants progressed to CSF+/PET+, whereas at that time only one participant exhibited suprathreshold early to intermediate stage tau pathology based on [18F]flortaucipir PET and none showed widespread neocortical uptake (i.e. Braak stage V/VI regions). This finding has at least two implications. First, as the majority of CSF+/PET-participants did not progress to CSF+/PET+ within 5 years, this indicates that in the majority of cases the CSF+/PET- amyloid-β status lasts for several years. Second, accumulation of sufficient amyloid-β detectable by both CSF and PET seems to precede significant accumulation of tau pathology.45 However, we also found a correlation between baseline regional amyloid-β PET and tau pathology in the CSF+/PET- group, suggesting that there
already might be interaction present between amyloid-β and tau. This supports previous work, emphasizing the importance of considering subthreshold accumulation of pathology to better understand disease mechanisms of early preclinical stages of AD.\textsuperscript{46–48}

Our study has some limitations. Although ADNI is one of the largest cohorts with both available amyloid-β PET and CSF analysis, only a relatively small number of participants with discordant CSF/PET amyloid-β status were available. Second, our main outcome measures of tau pathology based on CSF and PET were assessed at different time-points. Although that reduces the direct comparability of these findings, they also complement each other and allow to measure tau pathology both at baseline and several years later. Additionally, relatively short follow-up periods were available for both CSF tau measures and [\textsuperscript{18}F]flortaucipir PET. Therefore, it is possible, that with longer follow-up periods, subjects with discordant amyloid-β status might show diverging trajectories compared to the CSF-/PET- group. Our interpretation of the study could also be afflicted by the possibility that CSF+/PET- status might reflect a different subtype of AD, although no evidence for that exists. Finally, cut-offs of biomarkers as well as defining amyloid-β PET status based on global SUVR are important considerations when evaluating these results. As suboptimal cut-offs might result in misclassification,\textsuperscript{49} we used applied widely used and validated cut-offs for both PET and CSF.

In conclusion, our findings indicate that a sufficient amyloid-β load detectable by both PET and CSF is required before substantial tau deposition emerges. Subjects with CSF+/PET- amyloid-β profile are at a significantly earlier clinical and biological disease stage than those with CSF+/PET+, and have a distinctly better prognosis for at least five years.

A,B,C,D indicate differences (p < 0.05) from other groups: A – difference from CSF-/PET-; B – difference from CSF+/PET-; C – difference from CSF-/PET+; D – difference from CSF+/PET+. Baseline diagnosis was either cognitively normal or mild cognitive impairment (MCI). Cognitive test scores were compared while adjusting for age, sex and education. False discovery rate was used to correct for multiple comparison. SUVR - standardized uptake value ratios.
Figure 1. Accumulation of amyloid-β measured by $[^{18}\text{F}]$florbetapir positron emission tomography

Results obtained from linear mixed models, with the colors indicating β-coefficients relative to the CSF-/PET- group. The three sections show the difference between the group of interest (CSF+/PET-, CSF-/PET+ or CSF+/PET+) and CSF-/PET-. The first column shows the β-coefficient for the baseline effect of the CSF/PET group when using whole cerebellum as the reference region. The second and third columns show the β-coefficients for the interaction between CSF/PET group and time as the longitudinal change when using whole cerebellum or composite white matter as the reference, respectively. Only regions with p<0.05 are shown. Image was created using the ggseg package in R.

Figure 2. Longitudinal trajectories of tau pathology and cognition

Results obtained from linear mixed models investigating the effect of amyloid-β CSF/PET discordance on A tau pathology assessed by CSF t-tau and p-tau, B tau pathology based on regional $[^{18}\text{F}]$flortaucipir PET, and C cognitive trajectories measured by MMSE, ADNI memory and executive composite scores. CSF tau was assessed from baseline to median 2.0 years; $[^{18}\text{F}]$flortaucipir PET was first performed a median of 5.2 years after baseline and was followed up a median of 1.3 years later; cognitive tests were assessed at baseline, and followed up for a median of 4.2 years. Difference from CSF+/PET+ is illustrated by black triangles (for CSF+/PET-) or circles (for CSF-/PET+) with the number of symbols indicating statistical difference (one: p<0.05; two: p<0.01; three: p<0.001). Symbols on the left side of a plot show difference in intercept (main effect of CSF/PET group in the model), and symbols on the right side show a difference in slope (interaction between CSF/PET group and time). CSF+/PET-participants also had at baseline worse executive functioning than participants in the CSF-/PET- group (p=0.034). Image was created using the ggeffects package in R.

Figure 3. Kaplan-Meier curves for clinical progression

Results obtained from the Kaplan-Meier estimate investigating the association between amyloid-β CSF/PET profile and clinical progression from CN to MCI or dementia, or from MCI to dementia (A) and progression from CN or MCI to dementia (B). Tables below the figures report per year the number of participants with available follow-up data.
Figure 4. Correlation between baseline $^{18}$F-florbetapir PET and tau pathology based on CSF and PET

Plotted is the association between $^{18}$F-florbetapir PET, based on A total composite and B early accumulating regions composite on the x axis, and cross-sectional tau pathology, measured by either CSF t-tau or p-tau at baseline or $^{18}$F-flortaucipir PET median of 5.2 years after baseline on the y axis. R² and p values are reported from the from linear regression models, which were also adjusted for the times between baseline $^{18}$F-florbetapir PET and the outcome modality.
