15

16 The outbreak of Coronavirus Disease 2019 (COVID-19) caused by the severe acute
17 respiratory syndrome coronavirus 2 (SARS-CoV-2) emerged in Wuhan, December
18 2019, and continuously poses a serious threat to public health. Our previous study has
19 shown that cytokine storm occurred during SARS-CoV-2 infection, while the detailed
20 role of cytokines in the disease severity and progression remained unclear due to the
21 limited case number. In this study, we examined 48 cytokines in the plasma samples
22 from 53 COVID-19 cases, among whom 34 were severe cases, and the others

23 moderate. Results showed that 14 cytokines were significantly elevated upon
24 admission in COVID-19 cases. Moreover, IP-10, MCP-3, and IL-1ra were
25 significantly higher in severe cases, and highly associated with the PaO₂/FaO₂ and
26 Murray score. Furthermore, the three cytokines were independent predictors for the
27 progression of COVID-19, and the combination of IP-10, MCP-3 and IL-1ra showed
28 the biggest area under the curve (AUC) of the receiver-operating characteristics (ROC)
29 calculations. Serial detection of IP-10, MCP-3 and IL-1ra in 14 severe cases showed
30 that the continuous high levels of these cytokines were associated with disease
31 deterioration and fatal outcome. In conclusion, we report biomarkers that closely
32 associated with disease severity and outcome of COVID-19. These findings add to
33 our understanding of the immunopathologic mechanisms of SARS-CoV-2 infection,
34 providing novel therapeutic targets and strategy.

35

36 Coronaviruses are the largest known viruses with a single positive- sense genome of
37 about 31Kb which could infect a wide range of different species, and mainly infect
38 respiratory and intestinal tract causing a wide range of symptoms ¹. Six members of
39 coronaviruses that have been found to infect human beings, including HCoV-229E,
40 HCoVOC43, HCoV-NL63, and HCoV-HKU1, Severe Acute Respiratory Syndrome
41 coronavirus (SARS-CoV) and Middle East Respiratory Syndrome coronavirus
42 (MERS-CoV) ^{1,2}. Until recently, human infection with the novel severe acute
43 respiratory syndrome coronavirus 2 (SARS-CoV-2) was firstly identified in late
44 December, 2019, in Wuhan, China ^{3,4}. As of Feb. 29, 2020, a total of 79824
45 Coronavirus Disease 2019 (COVID-19) cases with 2870 fatal cases were reported ⁵.
46 Furthermore, another 53 countries have also reported COVID-19 cases, posing a
47 serious threat of public health ⁶. Studies have revealed that pneumonia is the most
48 common complications following SARS-CoV-2 infection, and followed by acute
49 respiratory distress syndrome (ARDS) ^{7,8}. Inflammation is the body's first coordinated
50 line of defense against tissue damage caused by either injury or infection, involving
51 activating both the innate and adaptive immune responses ⁹. However, exuberant
52 immune responses following infection have been described as a cytokine storm,
53 associated with excessive levels of proinflammatory cytokines and widespread tissue
54 damage including ARDS ¹⁰.

55 Cytokine storm has been found during the infection of influenza viruses ¹¹⁻¹⁶ as
56 well as coronaviruses ¹⁷⁻²⁴, and contributes to acute lung injury and development of
57 ARDS ². Preliminary studies have shown that SARS-CoV-2 infection triggers
58 cytokine storm, and results in the increase of a variety of cytokine/chemokine ^{25,26}.
59 However, the detailed role of cytokines in diseases severity and progression remains
60 unknown. In this study, we recruited 53 COVID-19 cases with 34 severe cases and 19

61 moderate cases defined according to China National Health Commission Guidelines
62 for Diagnosis and Treatment of SARS-CoV-2 infection, and analyzed the plasma
63 cytokine/chemokine profile in detail. Most of the severe cases (73.5%) were \geq 60
64 years-old, while the moderate cases were mainly in the group of 16-59 years-old
65 (63.2%) (Table S1). The initial symptoms, co-existing chronic medical conditions,
66 intervals of illness onset to admission and antiviral treatment were similar between
67 the two groups. Complications occurred more frequently in the severe cases,
68 including ARDS, respiratory failure, hepatic and renal insufficiency (Table S1). A
69 complete blood count with differential was assessed for each patient either on the date
70 of hospital admission, or at the earliest time-point and thereafter (Table 1). The
71 percentage of lymphocyte (LYM) and neutrophil (NEU) as well as the CD4 and CD8
72 counts were significantly lower in the severe cases, indicating a possible dysfunction
73 of immune responses.

74 Then the expression profile of cytokines/chemokines of COVID-19 cases upon
75 admission was analyzed. Elevated concentrations of both pro- and anti-inflammatory
76 cytokines were observed in these cases including IFN- γ (interferon, IFN), IL-1ra
77 (interleukin, IL), IL-2ra, IL-6, IL-10, IL-18, HGF (hepatocyte growth factor), MCP-3
78 (monocyte chemotactic protein-3), MIG (monokine induced gamma interferon),
79 M-CSF (macrophage colony stimulating factor), G-CSF (granulocyte
80 colony-stimulating factor), MIG-1a (macrophage inflammatory protein 1 alpha)
81 CTACK (cutaneous T-cell-attracting chemokine) and IP-10 (interferon gamma
82 induced protein 10), when compared with healthy control, indicating that cytokine
83 storm occurred following SARS-CoV-2 infection (Figure 1) as previously reported^{3,25}.
84 Similar phenomenon was also observed in SARS-CoV¹⁷⁻²¹ and MERS-CoV²²⁻²⁴
85 infected patients, despite that the expression profiles were virus specific. Meanwhile,

86 we compared the plasma cytokine/chemokine levels collected from severe and
87 moderate cases at different days after illness onset (d.a.o). The results showed that
88 most of the cytokines were comparable between the two groups and maintained high
89 level even at the later stage of the disease (≥ 15 d.a.o). However, IP-10, MCP-3,
90 IL-1ra and MIG were significantly higher in samples from severe cases in all the three
91 groups of sample collection time, even though statistical significance was not
92 observed in IL-1ra and MIG. Notably, IP-10 in the severe cases possessed a high and
93 similar expression level at all groups of sample collection time. On the contrary, IP-10
94 in moderate cases was significantly lower and further decreased a lot at ≥ 15 d.a.o.
95 Moreover, comparison of these fourteen cytokines between the severe and moderate
96 cases showed significantly higher levels of IP-10, MCP-3 and IL-1ra in the severe
97 cases (Figure 1). Spearman rank coefficient correlation analysis showed that IP-10,
98 MCP-3 and IL-1ra expression levels were highly correlated with PaO₂/FaO₂ and
99 Murray scores. Interestingly, the viral load (displayed as Ct values) showed obvious
100 correlation with only IP-10, while not MCP-3 and IL-1ra, as well as the PaO₂/FaO₂
101 and Murray scores (Figure S2). Our previous study has found that the viral shedding
102 in COVID-19 cases is complicated and the viral loads obtained from the regularly
103 used upper respiratory specimens might not consistent with the real case, especially
104 for the severe cases²⁷. Meanwhile, the main distribution of viruses in the severe and
105 moderate cases were also different, which might influence the induction of cytokines
106 as well. Indeed, studies have found that high viral loads in some types of viral
107 infections correlated with severe diseases²⁸⁻³⁰, while not for all of them³¹. These
108 results suggested that the production of specific cytokines while not the viral burden
109 might play central in the pathogenesis COVID-19.

110 We further analyzed whether these cytokines could be used as predictors for the

111 disease severity and progression of COVID-19. Firstly, we calculated the receiver
112 operating characteristic (ROC) of each single cytokine using the expression levels
113 upon admission. Results showed that the area under the curve (AUC) of the ROC was
114 0.915, 0.765 and 0.792 for IP-10, MCP-3 and IL-1ra, respectively (Figure 3). Then
115 we tested the different combination of these cytokines for the prediction of disease
116 progression. Combinations of the three cytokines showed the highest AUC of 0.943,
117 followed by the combination of IP-10 and MCP-3 (0.927) as well as the combination
118 of IP-10 and IL-1ra (0.923) (Figure 3). Furthermore, we analyzed the serial change of
119 the three cytokines in 14 severe cases. In the two fatal cases (cases 1 and 2), the
120 expression levels were significantly high upon admission and maintained high levels
121 during the disease progression. Meanwhile, five cases (cases 7~9, 11 and 13) with
122 continuously high levels of these cytokines, especially IP-10 and MCP-3, were still in
123 critical condition. On the contrary, cases 3~6, 10, 12 and 14 with lower levels or
124 significantly decreased levels of these cytokines showed an obvious
125 improvement of the disease, and became moderate cases (cases 4, 10, 12 and 14) or
126 discharged from hospital (cases 3, 5, 6 and 10). These results indicated that these
127 three cytokines could be considered as biomarkers to predict disease progression and
128 outcome of SARS-CoV-2 infections.

129 Cytokine storm with uncontrolled proinflammatory responses induce significant
130 immunopathology and severe disease outcomes during some viral infections,
131 indicating an important role in the pathogenesis of these viruses ^{2,32}. Accordingly, not
132 only the pathogens but also the pathogen induced cytokine storm should be
133 considered during the treatment. Therapy strategy with a combination of antimicrobial
134 and immunotherapy may produce a more favorable outcome ⁹. Corticosteroids which
135 could downregulate proinflammatory cytokine transcription and subsequently inhibit

136 the cytokine storm³³, and the antiviral cytokine interferon- α were widely used during
137 the treatment of COVID-19^{8,34}. However, use of high-dose corticosteroids has been
138 shown to be associated with an increase in mortality and significantly longer
139 durations of viral shedding in H7N9 infected patients³⁵, which is of concern. The
140 results of our study suggested a crucial role of IP-10 in the pathogenesis of
141 SARS-CoV-2, which has also been shown to be associated with disease severity of
142 H5N1, H1N1, SARS-CoV and MERS-CoV^{16,24,29,36}. A recent study has found that
143 IP-10 (CXCL10)-CXCR3 signaling appears to be a critical factor for the exacerbation
144 of the pathology of ARDS³⁷. Thus, modulators such as antibody targeting IP-10
145 might be a promising therapeutic strategy in the treatment of the acute phase of ARDS
146 to ameliorates acute lung injury as shown in H1N1 mouse model^{37,38}.

147 In summary, we compared the differences of cytokines profiles between severe and
148 moderate COVID-19 cases, and found that IP-10, MCP-3 and IL-1ra were
149 significantly associated with disease severity and progression of COVID-19. Our
150 results added to our understanding of the immunopathologic mechanisms of
151 SARS-CoV-2 infection, and suggest a novel therapeutic strategy using modulators or
152 antibodies against theses cytokines, especially IP-10.

153 **METHODS**

154 **Patient information and data collection**

155 Subjects presented in this study were hospitalized COVID-19 patients (N=53), among
156 whom 34 were defined as severe cases according to China National Health
157 Commission Guidelines for Diagnosis and Treatment of 2019-nCoV infection.
158 Healthy controls (N=8) were also included. Clinical information and laboratory result
159 were collected at the earliest time-point after hospitalization. The study protocol was
160 approved by the Ethics Committees of Shenzhen Third People's Hospital
161 (SZTHEC2016001). Informed consents were obtained from all patients or patients
162 family members. The study was conducted in accordance with the International
163 Conference on Harmonisation Guidelines for Good Clinical Practice and the
164 Declaration of Helsinki and institutional ethics guidelines.

165 **Quantitative reverse-transcriptase polymerase chain reaction (qRT-PCR)**

166 qRT-PCR were done as previously reported^{26,34}. In brief, throat swabs, nasal swabs,
167 sputum and BALF specimens were collected from laboratory-confirmed COVID-19
168 cases upon admission and thereafter. Viral RNAs were extracted from clinical
169 specimens using the QIAamp RNA Viral Kit (Qiagen, Heiden, Germany). A China
170 Food and Drug Administration (CDFA) approved commercially kit (GeneoDX Co.,
171 Shanghai, China) were used for the detection of SARS-CoV-2 specific RNAs.
172 Samples with a cycle threshold (Ct) value ≤ 37.0 were considered putatively positive.
173 Samples whose Ct was higher than 37 were re-tested and considered positive if Ct
174 was ≥ 37 but ≤ 40 and negative if viral RNAs were undetectable on the second test.

175 **Disease severity classification**

176 Disease severity classification and Murray Score calculation were evaluated as
177 previously reported ²⁶. Severity of 2019-nCoV infection was graded according to
178 China National Health Commission Guidelines for Diagnosis and Treatment of
179 SARS-CoV-2 infection. Laboratory confirmed patients with fever, respiratory
180 manifestations and radiological findings indicative of pneumonia were considered
181 moderate cases (COVID-19-M). Laboratory confirmed patients who met any of the
182 following were considered to have severe COVID-19 (COVID-19-S): 1) respiratory
183 distraction (respiration rate \geq 30/min; 2) resting oxygen saturation \leq 93%, or 3) arterial
184 oxygen partial pressure (PaO₂) / fraction of inspired oxygen (FiO₂) \leq 300 mmHg (1
185 mmHg = 0.133 kPa). Laboratory confirmed patients who had any of the following
186 were considered in critical condition: 1) respiratory failure requiring mechanical
187 ventilation, 2) shock, or 3) failure of other organs requiring intensive care unit (ICU).

188 **Quantification of hypoxia and Murray Score**

189 The partial pressure of oxygen (PaO₂) in arterial blood taken from the patients at
190 various time-points after hospitalization is measured by the ABL90 blood gas
191 analyzer (Radiometer). The fraction of inspired oxygen (FiO₂) is calculated by the
192 following formula: $FiO_2 = (21 + \text{oxygen flow (in units of l/min)} \times 4) / 100$. The
193 PaO₂/FiO₂ ratio (in units of mmHg) is calculated by dividing the PaO₂ value with the
194 FiO₂ value. A PaO₂/FiO₂ ratio less than or equal to 100 mmHg is considered one of
195 the criteria for severe acute respiratory distress syndrome (ARDS). Murray Score
196 were calculated as reported ³⁹.

197 **Cytokine and chemokine measurements**

198 The plasma of patients with laboratory-confirmed COVID-19 cases (N=53) were

199 collected at the earliest possible time-point after hospitalization and thereafter. The
200 plasma of healthy subjects (N=8) were included as the negative control group. The
201 concentrations of 48 cytokines and chemokines were measured using Bio-Plex Pro
202 Human Cytokine Screening Panel (Bio-Rad) as previously reported^{15,26}.

203 **Statistical analysis**

204 Fisher exact test was used to compare the indicated rates between the moderate and
205 severe cases. Mann-Whitney U test was used to compare plasma cytokine levels
206 between two groups. The Spearman rank correlation coefficient was used for linear
207 correlation analysis between the expression level of plasma cytokine and PaO₂/FiO₂
208 ratio, Murray score as well as viral loads of COVID-19 cases. The area under the
209 receiver operating characteristic (ROC) curve (AUC) of plasma cytokine levels was
210 estimated for the moderate and severe cases. All statistical tests were calculated using
211 SPSS 20.0 for Windows (IBM, Chicago, USA). *P value* less than 0.05 was considered
212 statistically significant.

325 **Acknowledgement**

326 This work was supported by the National Natural Science Foundation of China (Grant
327 81802004) and the National Science and Technology Major Project (Grants
328 2018ZX10711001, 2017ZX10204401 and 2017ZX10103011), Shenzhen Science and
329 Technology Research and Development Project (Grants JCYJ20180228162201541,
330 202002073000001) Sanming Project of Medicine in Shenzhen (SZSM201412003,
331 SZSM201512005).

332 **Author contributions**

333 Y. Liu, L. Liu, Z. Zhang and Y. Yang conceived and guided the project. Y. Yang, C.
334 Shen, M. Yang carried out the experiments and analyzed the data. J. Li, J. Yuan, F.

335 Wang, Z. Wang, M. Cao, W. Wu, R. Zou, Y. Li, L. Xing, L. Peng, J. Wei, H. Zheng, Z.
336 Xu, and H. Wang collected clinical samples and the data. Y. Yang wrote the
337 manuscript. All the authors have read and approved the manuscript.

338 **Competing interests**

339 The authors declare no competing interests.

340 **Figure legends**

341 **Figure 1. Comparison of serum cytokine/chemokine concentrations between**
342 **healthy volunteers and COVID-19 cases.** Samples from severe (N=34) and
343 moderate (N=19) COVID-19 cases were collected at the earliest possible time-point
344 after hospitalization for assays measuring the concentrations of 48 cytokines and
345 chemokines, and healthy subjects (N=8) were involved as control. Values were
346 graphed on a logarithmic scale and presented in units of pg/mL. *P values* between
347 0.01-0.05, 0.001-0.01 and 0.0001-0.001 were considered statistically significant (*),
348 very significant (**) and extremely significant (***), respectively, whereas ns
349 represents not significant.

350

351 **Figure 2. IP-10, MCP-3 and IL-1ra expression levels were highly correlated with**
352 **PaO₂/FiO₂ and Murray Score.** The expression levels of IP-10, MCP-3 and IL-1ra
353 measured from plasma samples collected upon admission and thereafter and the
354 corresponding PaO₂/FiO₂ and Murray Score at the same day were analyzed using
355 spearman rank correlation analysis. The *r values* and *p values* were shown.

356

357 **Figure 3. The ROC curve of plasma cytokine levels for patients with mild and**
358 **severe SARS-CoV-2-infections.** The receiver operating characteristic (ROC) curve
359 was calculated using SPSS. The area under the curve (AUC) of ROC for IP-10,
360 MCP-3 and IL-1ra was estimated using the expression levels upon admission. The *P*
361 values of all AUC for the three cytokines were less than 0.05.

362

363 **Figure 4. Dynamic changes of IP-10, MCP-10 and IL-1ra in 14 severe cases of**
364 **COVID-19 with different outcome and progression.** The expression levels
365 measured at the indicated time-points of 14 severe cases were shown. The fatal cases
366 were marked in red. Cases in critical condition were marked in blue, and the others
367 were cases with moderate disease or discharged at present.

368

369 **Figure S1. Comparison of the significantly elevated cytokines measured at**
370 **different days post illness onset between severe and moderate COVID-19 cases.**
371 The expression levels of 14 significantly elevated cytokines measured at different
372 days post illness onset were shown and compared between the severe and moderate
373 COVID-19 cases. *P values* between 0.01-0.05, 0.001-0.01 and 0.0001-0.001 were
374 considered statistically significant (*), very significant (**), and extremely significant
375 (***), respectively, whereas ns represents not significant.

376

377 **Figure S2. Correlations between viral load and the cytokines of IP-10, MCP-3**
378 **and IL-1ra, as well as PaO₂/FiO₂ and Murray Score.** The correlations between
379 viral load and the cytokines of IP-10, MCP-3 and IL-1ra, as well as PaO₂/FiO₂ and
380 Murray Score were analyzed using spearman rank correlation analysis. The *r values*
381 and *p values* were shown. The viral loads were indicated as Ct values, and lower Ct
382 values represented high viral load.
