Abstract

Background
The ongoing outbreak of 2019 novel coronavirus disease (COVID-19) is a global threat. Clarifying its clinical features such as risk factors for disease progression is a pressing issue. We analyzed the difference between non-severe and severe cases with COVID-19 as a result of the mass infection on a cruise ship “Diamond Princess” in Japan.

Methods
In this retrospective, single-center study, total 104 cases of laboratory-confirmed COVID-19 were enrolled from the mass infection on the cruise ship from 11th to 25th Feb, 2020, at Self-Defense Forces Central Hospital in Japan. Clinical records, laboratory data, and radiological findings were collected and analyzed. Clinical outcomes were followed up until 26th Feb, 2020.

Findings
Of the 104 patients, 47 were male. The median age was 68 years. During the observation period, eight patients deteriorated into the severe cases. Finally, 76 and 28 patients were classified as non-severe (asymptomatic, mild), and severe cases, respectively. Chest CT abnormalities were found in 43 in non-severe cases and 23 in severe cases. The prevalence of consolidation on chest CT scan and lymphopenia on the admission day was significantly higher in severe cases and in the eight cases which worsened into severe disease during the observation period.

Interpretation
The high proportion of non-severe cases corrects the assessment of the trend of the outbreak. Consolidation on chest CT scan and lymphopenia were possible risk factors for deterioration of COVID-19 and contribute to the clinical management.

Funding
Not applicable.

Research in context

Evidence before this study
We looked into PubMed database for articles published in English up to 1st, Mar, 2020, using the keywords “novel coronavirus”, “2019 novel coronavirus”, “2019-nCoV”, “Severe acute respiratory syndrome coronavirus 2”, “SARS-CoV2”, “COVID-19”, “mass infection”, “herd infection”, “cruise ship”, “Diamond Princess”, “asymptomatic” and “subclinical”. There were no published clinical studies of featuring COVID-19 as a result of mass infection of cruise ship. We found a published researches entitled “Characteristics of COVID-19 infection in Beijing.”, and “Radiological findings from 81 patients with COVID-19 pneumonia in Wuhan, China: a descriptive study” comparing patients with COVID-19 between asymptomatic, mild, and severe cases. However, above researches
did not describe the marker of deterioration, or the risk factors for disease progression.

**Added value of this study**

We presented a high proportion of asymptomatic and mild cases in patients infected with severe acute respiratory syndrome coronavirus 2 (SARS-CoV2). On the admission day, the prevalence of consolidation detected by CT scan and lymphopenia were significant higher in severe cases and in cases which deteriorated into severe cases during the observation period. Consolidation on CT scan and lymphopenia reflect the disease progression. This report contributes to the improvement of the epidemiological and clinical management of COVID-19.

**Implications of all the available evidence**

There is a high prevalence of non-severe cases in patients infected with COVID-19 as a result of the mass infection on a cruise ship. The prevalence of asymptomatic and mild cases of COVID-19 contributes to the further assessment on the trend of outbreak. Consolidation detected by CT scan and lymphopenia are useful for the markers of disease progression.

**Introduction**

The 2019 novel coronavirus disease (COVID-19) is caused by a novel coronavirus – severe acute respiratory syndrome coronavirus 2 (SARS-CoV2). The first case was reported in Wuhan, China, in December 2019, and the ongoing outbreak has been declared by the World Health Organization as a Public Health Emergency of International Concern. Since the specific treatment for COVID-19 is unknown, detection of the patients who are at high risk of severe illness is necessary in order to prepare sufficient supportive therapy. Also, explosive increase in patients caused a collapse of health care system. Therefore triage of the patients and transportation to the proper facilities are required. The knowledge of the clinical characteristics of the disease and pathogenicity of the virus is increasingly accumulated. However, detail of the clinical characteristics is still unknown and most of the articles previously printed are mainly focused on the severe cases of COVID-19. In Japan, a large number of infection among passengers and crew members of the cruise ship “Diamond Princess” occurred in Feb, 2020. By 1st March, 2020, over 700 people were laboratory-confirmed with SARS-CoV2 infection. All symptomatic and asymptomatic cases were referred to the medical institutions designated for infectious diseases in accordance with Infectious Diseases Control Law of Japan. Approximately 15% of the laboratory-confirmed cases were admitted to Self-Defense Forces Central Hospital in Japan.

The prevalence of asymptomatic and mild cases of COVID-19 contributes to the assessment of epidemic trend. In the clinical settings, identifying the patients who are at risk of deterioration is essential. For these reasons, understanding of the differences between non-severe (asymptomatic and mild) cases and severe cases is required.

Therefore, we retrospectively collected and analyzed detailed clinical findings in hospitalized cases.
with COVID-19 of the cruise ship outbreak, including asymptomatic/mild and severe symptomatic cases, at the Self-Defense Forces Central Hospital in Japan.

Methods

Study design and patients
We conducted a retrospective review on the medical records of 104 laboratory-confirmed patients with COVID-19 who were referred to the Self-Defense Forces Central Hospital in Japan, since 11th to 25nd Feb 2020. In the cruise ship, all patients were examined under quantitative reverse transcription polymerase chain reaction (qRT-PCR) or nested polymerase chain reaction (PCR) for SARS-CoV2 in the pharyngeal swab or sputum according to the recommendation by the National Institute of Infectious Disease at the public health institute. This study was reviewed and approved by the Japan Self-Defense Forces Central Hospital (approval number 01-011). Both written and oral informed consent was obtained from each enrolled patient.

Data collection
We retrospectively collected patient information from the electronic medical records of our hospital, including clinical records, laboratory findings, and chest CT scans. All information were collected and reviewed by two study investigators (ST and KI).

Definitions
The geographical regions were classified according to the standard country or area codes for statistical use (M49) by the United Nations Statistics Division. Asymptomatic cases were defined as patients with no history of clinical signs and symptoms. Severe symptomatic cases were defined as patients showing clinical symptoms of pneumonia (dyspnea, tachypnea, saturation of percutaneous oxygen (SpO2) <93%, and patients’ need for oxygen therapy). Other symptomatic cases were classified as mild cases.

Statistical analysis
Continuous variables were expressed as mean standard deviation (SD) or median interquartile range [IQR], and compared with under the T-test or Wilcoxon rank-sum test for parametric or non-parametric data, respectively; categorical variables were expressed as number (%) and compared by χ2 test or Fisher’s exact test. Multivariable logistic regression analysis was used for multivariate analysis. The final multivariable logistic regression models were adjusted for age, sex, smoking, and any underlying disease. A two-sided p-value of less than 0.05 was considered statistically significant. All statistical analyses were calculated using Stata13.

Role of the funding source
There was no funding source for this study.

Result
During the observation period, total 107 laboratory-confirmed patients with COVID-19 from the cruise ship were hospitalized at the Self-Defense Forces Central Hospital in Japan. Three patients were excluded from this study because of their withdrawal to join this study. Therefore, the remaining 104 patients were analyzed. Clinical history, physical examination and chest CT scan were evaluated on the admission day, and blood tests were conducted within two days. The characteristics of the 104 patients are presented in Table 1. The age range was 25–93 years (median, 68 years; IQR, 46.75–75), and 47 patients (45.2%) were male. The most common nationality of patients was Eastern Asia, which included Japan and China. The observation period is from three to fifteen days (median, 10; IQR, 7–10 day). Fifty two patients (50.0 %) had comorbidities.

The clinical findings and severity of the patients before and after admission are shown on Table 2. Of the 104 patients, the most common clinical signs and symptoms presented before the admission were fever (28.8%) and cough (27.9%). On the admission day, 43 patients (41.3%) didn’t show any symptoms; therefore, these patients were classified as asymptomatic. Forty-one patients (39.4%) were classified as mild cases, and 20 patients (19.2%) were severe cases. During the observation period, 80 new clinical signs and symptoms arose. Seven asymptomatic cases were reclassified as mild cases. Three asymptomatic cases and five mild cases required oxygen therapy because of the pneumonia of COVID-19; thus, they were reclassified as severe cases. The confirmed classification of severity at the end of the observation is; 33 patients (31.7%) as asymptomatic, 43 patients (41.3%) as mild, and 28 patients (26.9 %) as severe. Describing about the eight patients who deteriorated and reclassified as severe cases, the age range was 42–87 years (median, 70 years; IQR, 70–77), and five patients (62.5%) were male. The period of deterioration from onset was 1- 5 days (median, 4 days; IQR, 2.5-5). Also, of all the patients, 14 patients (13.5%) needed oxygen therapy, and a patient required mechanical ventilation. None of the patients died during the observation period.

The differences in clinical, laboratory, and radiographic abnormality on the admission day between non-severe cases and severe cases were analyzed. There were no significant differences observed in the distribution of age, sex, and comorbid condition between two groups (Table 3). Of the 76 non-severe patients, 43 patients (56.6%) manifested the abnormal findings on CT scan with various patterns. (Figure 1). In univariate analyses, the prevalence of CT abnormality detected on the admission day was significantly higher in the severe cases than in non-severe cases (85.2% vs 56.6%; \( p = 0.03; \) OR, 3.53; 95% CI; 1.21-10.27). Significant differences in the prevalence of the CT pattern were found between severe and non-severe cases as follows: bilateral lung findings (57.1% vs 28.9%; \( \text{OR, 3.27; 95\% CI; 1.33–8.06; } p = 0.01 \)), multifocal ground-glass opacity (GGO) (63.0% vs 34.2%; \( \text{OR, 2.97; 95\% CI; 1.21–7.26; } p = 0.02 \)), and consolidation (48.1% vs 19.7%; \( \text{OR, 3.52; 95\% CI; 1.38–8.96; } p = 0.01 \)). With regard to blood tests, the elevation of aspartate transaminase (AST) \( \geq 38 \text{ IU/dL (32.1\% vs 11.8\%; OR, 3.52; 95\% CI; 1.22-10.12; } p = 0.01 \) and depletion of lymphocyte count <1,200 (/μL) (lymphopenia) (57.1% vs 25.0%; \( \text{OR, 4.00; 95\% CI; 1.61-9.95; } p < 0.01 \)) in severe cases was significantly higher than in non-severe cases. Subsequently, the patients...
who worsened to severe cases during the observation period (n=8) were compared with the patients
in non-severe cases (n=76). In the patients who deteriorated, eight patients (100.0%) presented the
radiographical abnormality on CT in prior to the typical pneumonia symptoms (Figure 2).
Consolidation on chest CT scan and lymphopenia were found in six (75.0%) and five patients
(62.5 %), respectively. In univariate analyses, the prevalence of consolidation (75.0% vs 19.7%; OR,
12.20; 95% CI; 2.23–66.59; p = 0.04) and lymphopenia (62.5% vs 25.0%;OR, 5.00; 95% CI;
1.10–22.92; p = 0.04) were found to be significant higher in the patients who worsened to severe
cases.
In multivariate analysis, the prevalence of consolidation detected by chest CT scan (adjusted OR:
3.24; 95% CI; 1.04-10.40; p = 0.04), and lymphopenia (adjusted OR, 4.30; 95% CI; 1.50-13.75; p <
0.01) were found to be significant higher in severe cases.

Discussion

In the outbreak of COVID-19 on the cruise ship “Diamond Princess,” members of the cruise ship
were tested by PCR for SARS-CoV2 and all laboratory-confirmed cases were referred to the
hospitals. This situation is worthy to note because we observed the clinical course of even
asymptomatic or mild symptomatic patients, which have not been investigated in the reports
previously published. 2-5
The possible risk factors for deterioration of COVID-19 have been unclear, because patients do not
visit hospitals if they are asymptomatic or only mild symptomatic. Based on the previous findings of
COVID-19 in China, old age, male sex, and presence of comorbidities may be risk factors for disease
progression and poor prognosis.1 In this study, the prevalence of consolidation detected by chest CT
scan and lymphopenia were significantly higher in severe cases and in the cases that worsened to
severe condition during the observation period than in non-severe cases (p < 0.05). Therefore,
consolidation and lymphopenia are considered as possible risk factors for disease progression of
COVID-19. Pan F, et al. and Shi H, et al. reported that the pattern of abnormal lung findings was
varied from GGO into consolidation during the time course of COVID-19 9, and the appearance of
consolidation became more frequent in patients within 1-3 weeks after symptom onset. 10 Previous
reports showed 55% of patients with COVID-19 developed dyspnea a median of 8 days (IQR,
5.0–13.0) after symptom onset, 1 thus, the timing of appearance of consolidation on CT scan is
associated with the timing of deterioration of the disease. Generally, consolidation is easily
detectable in chest X-ray. It may be useful for evaluation for risk of the disease progression in the
patients with COVID-19 in the setting with limited resources,
With regard to blood tests, lymphopenia is a common feature in symptomatic COVID-19 11,12, and
this can be caused by either direct effect of the SARS-CoV2 or cytokines. Lymphopenia was also
frequently found in SARS 13, and was considered as a marker of disease activity. 14 Our findings
suggest that lymphopenia may also reflect the disease progression and lead a new insight into the
phenotype and pathogenicity of SARS-CoV2.
CT scan showed a high prevalence of abnormality in lungs in non-severe cases (56.6 %) and severe
cases (85.1 %), and that findings are also seen even in asymptomatic cases. Shi H, et al. also
mentioned these asymptomatic abnormal lung findings in their report focusing on the radiological
findings on CT scan of COVID-19 cases. This interesting clinical feature of the SARS-CoV2
infection has not been reported in the SARS-CoV or Middle East respiratory syndrome coronavirus
(MERS-CoV). All of the eight patients, who reclassified as severe cases from non-severe case during
the observation period, presented CT abnormality in advance of the appearance of typical pneumonia
symptoms. Moreover, less than half of the patients had no obvious symptoms such as fever and
cough. These facts warn us that COVID-19 pneumonia progresses “silently” without any remarkable
symptoms. Assessment with the blood test and chest CT scan might lead to a successful devotion of
medical resources to the patients who have the risk of disease progression in the setting and mass
infection as well as in the normal clinical settings. On the other hand, majority of asymptomatic
cases with radiological abnormality on CT scan did not develop the severe pneumonia. The
difference of clinical outcomes may associate with their background, and genetic and pathogenic
diversity of SARS-CoV2. Understanding of its relevance to the duration of virus shedding or to the
incidence rate of secondary bacterial pneumonia is important for improvement of clinical
management. Further study is required to clarify this clinical impact in the asymptomatic and mild
patients with COVID-19.
It is important to determine the proportion of asymptomatic and mild cases to assess not only the risk
of subsequent outbreaks but also the future trends. Generally, asymptomatic and mild infections
contribute to herd immunity and its dampening effect on epidemic spread. However, the
prevalence of asymptomatic and mild cases of COVID-19 has not been elucidated because detection
of the asymptomatic case by RT-PCR is not realistic, except for the limited situation like a mass
infection. In this study, we showed that 73.0 % of the patients in the mass infection on a cruise ship
were asymptomatic and mild cases, and the proportion was higher than previously reported. However, the
sensitivity of RT-PCR is considered insufficient, and the accurate prevalence is still
underestimated. The serological screening by using specific antibody of COVID-19 is expected to
confirm our result. Many countries and institutions are using contact tracing in the surveillance of
COVID-19. However, it is suggested that the large number of asymptomatic and mild patients may
have been overlooked in the past.
Viral RNA was frequently detected through throat swabs or sputum even in asymptomatic and mild
symptomatic patients. In Germany and China, the transmission from an asymptomatic patient to
another person has been reported. Zou L, et al. showed that viral RNA was detected in the upper
respiratory specimen in asymptomatic patients over 11 days, and the viral load of an asymptomatic
patient was equivalent to that of symptomatic cases. Also, the fact that we found CT abnormality
even in the asymptomatic patients also suggest that they may have a certain amount of viral load.
Previous findings along with our results may support the evidence that asymptomatic patients also shed the SARS-CoV2 from the upper respiratory tract. Also, during the mass infection on the cruise ship, there was a possibility that both asymptomatic and symptomatic patients spread the SARS-CoV2. Further study is desired to clarify the transmission from an asymptomatic patient to another person.

The limitations of this study were the selection bias and small number of patients. We enrolled the ideal homogeneous clusters of relatively healthy person who can get aboard a cruise ship for a long term. However, our patient population and was not completely representative of patients in the normal clinical settings. In addition, there were only a few patients who deteriorated into severe cases from non-severe case during the observation period in this study. Therefore, further multicenter, multi-national cohort study is desired to determine the prediction marker of diseases progression.

**Conclusion**

Our study highlighted the high prevalence of asymptomatic and mild cases of COVID-19 as a result of mass infection on a cruise ship. Consolidation on CT scan and lymphopenia may reflect the risk of disease progression. Our findings contribute to estimate the future trend of outbreaks, better understanding of clinical course and improvement of the management of COVID-19. Further cohort study is needed to determine the prediction marker of diseases activity.

</tbody>
</table>

Data are n (%), or median [IQR], unless otherwise specified. OR, odds ratio; 95% CI, 95% confidence interval; GGO, ground-glass opacity; AST, aspartate aminotransferase; ALT, alanine aminotransferase; LDH, lactate dehydrogenase; CRP, C reactive protein.
Asterisk indicated the statistical significance.
