Abstract

A SEIR simulation model for the COVID-19 pandemic was developed (<http://covidsim.eu>) and applied to a hypothetical European country of 10 million population. Our results show which interventions potentially push the epidemic peak into the subsequent year (when vaccinations may be available) or which fail. Different levels of control (via contact reduction) resulted in 22% to 63% of the population sick, 0.2% to 0.6% hospitalised, and 0.07% to 0.28% dead (n=6,450 to 28,228).

There is pandemic spread of the new coronavirus “SARS-Cov-2”, causing the disease “COVID-19”, with the World Health Organization (WHO) reporting over 200,000 cases and over 8000 deaths on 19 March 2020 [1]. One approach to informing the potential health burden and relevant control measures for a new pandemic is to study its dynamics using mathematical models. Recently published mathematical modelling work on COVID-19 has reported that “in most scenarios, highly effective contact tracing and case isolation is enough to control a new outbreak of COVID-19 within 3 months” [2]. Another modelling study found that “combining all four interventions (social distancing of the entire population, case isolation, household quarantine and school and university closure) is predicted to have the largest impact, short of a complete lockdown which additionally prevents people going to work” [3]. Other such models have been used to estimate the impact of disease control measures in China [4, 5]. Given this background, we explore the potential health impact of the spread of the COVID-19 pandemic in a hypothetical European country of 10 million people to determine the potential impact of control measures, particularly to push the epidemic into a subsequent year, a time when a vaccine might become available.

Europe’s first cases of COVID-19 were reported to WHO on 25 January in France [6]. But 19 March there were 52 of these countries with reported cases, with 12 reporting 1000+ cases [1]. By this time major control interventions were in place in many of these countries [7].

In this modelling, we took the standard approach of using a deterministic SEIR model i.e., key compartments for: susceptible [S], exposed [E], infected [I], and recovered/removed [R]. We developed this model specifically for COVID-19. It is freely available online with a dashboard display to facilitate user interaction (<http://covidsim.eu>, peer review and should not be used to guide clinical practice. The Appendix).

details the parameters, derived variables and differential equations used in the CovidSIM model. Table A1 in the Appendix provides the input parameters used in the model, as based on available publications and best estimates used in the modelling work on COVID-19 to date (as known to us on 18 March 2020).

Our results suggest that pushing the peak of the epidemic into the next year, when assuming a low basic reproduction number (R_0) of only 1.5, was achievable with “general contact reduction” at levels of over 11% to over 27% (for differing time periods) (Table 1). Similarly, it was achievable for probabilities of isolating symptomatic cases in hospital in the range of over 18% to over 41% (Table 1). Using instead a possibly more realistic value of 2.5 for R_0 , the only way of shifting the epidemic peak into the next year with interventions lasting for nine months, was if: (i) over 65% of contacts were reduced; or (ii) if the probability of cases being isolated in hospitals was extremely high at over 98%. Also for $R_0 = 3.5$, pushing the epidemic peak into the subsequent year was generally not possible, except if contact reduction was over 61% for the rest of the simulated year.

The feasibility of achieving high levels of contact reduction and case isolation is very uncertain – especially around sustaining these for long periods of time. At least in the short-term China has used intensive containment measures successfully as per the findings of the WHO-China Joint Mission Report [8]. This report stated that: “China has rolled out perhaps the most ambitious, agile, and aggressive disease containment effort in history.” While it is an open question around the generalisability of the Chinese approach to other jurisdictions [9], there is also evidence of containment success (as of late March 2020) outside mainland China, from Singapore, Hong Kong and Taiwan [10]. But for European countries currently with thousands of cases, it may be too late to adopt such intensive containment approaches and the best approach may simply be to apply less intense control measures that balance minimising health loss with minimising social and economic disruption (while also putting major resources into rapid vaccine development).

Figure 1 shows the scenarios at three different levels of R_0 when combined with “25% general contact reduction”. At $R_0 = 3.5$ the epidemic still peaks during the intervention period whereas for $R_0 = 2.5$ the peak is pushed into the post-intervention period. For $R_0 = 1.5$ the peak is nearly pushed into the subsequent year.

Figure 2 again demonstrates the importance of the timing of the intervention period. A higher level of contact reduction (at 50% vs 25%) more effectively suppresses the epidemic in the intervention period – but when the intervention period ends it causes a higher epidemic peak and a higher total health burden than for the 25% reduction (Table 2).

Considering the three levels of R_0 and the two levels of “general contact reduction” (at 25% and 50%) resulted in: 22% to 63% of the population sick, 8.8% to 25.1% seeking a medical consultation, 0.2% to 0.6% needing to be hospitalised, 5,500 to 15,682 people needing critical care (in an ICU), 2,750 to 7,841 requiring ventilators, and 6,450 to 28,200 dying (0.07% to 0.28% of the population) (Table 2). The worst scenario with 0.28% of the population dying, compares to Europe in the 1918 influenza pandemic where 1.1% died (2.64 million excess deaths) [11].

Based on the recent age distribution data from China [12], these hospitalisations and deaths from COVID-19 would particularly occur amongst older age-groups. Overall, the levels of health service demand in the more severe scenarios would be completely unprecedented for a modern European country.

This is one of the first SEIR modelling studies of this new pandemic disease COVID-19 and the

associated online simulation tool has advanced dashboard features and graphic visualisation of results that facilitate user engagement. Nevertheless, there are always limitations with modelling work. Some of these are discussed under issues with parameter uncertainty in Table A1, but here we note some of the more substantive limitations:

- There is still a high degree of uncertainty around many aspects of COVID-19 epidemiology. For example, the value of R_0 could conceivably be higher than the highest level in the scenarios we modelled (at $R_0 = 3.5$). Also, the case fatality risk (CFR) could be underestimated, especially if there was health system overload.
- The model was deterministic and not stochastic, though we largely offset this issue with modelling a wide range of scenarios. The lack of stochastic considerations mainly translates into increased uncertainty in the very early stages of epidemic spread, which then impacts on the timing of the peak.
- The model neither considers any long-term health damage to survivors (especially among risk patients) nor does it consider the hard-to-estimate health loss arising from untreated other health conditions as a result of having an overburdened health system. Likewise we do not consider the additional health harm to the health workers involved e.g., adverse mental health impacts arising from working during a pandemic [13, 14].

Some of these issues can be addressed when improved data becomes available on the epidemiology of COVID-19. Nevertheless, public health workers can consider using this model in their own countries and adapt the parameters according to local settings and as the epidemiological characteristics of COVID-19 are better ascertained.

Table 1: Threshold analyses for pushing the peak of the COVID-19 epidemic in the hypothetical European country into the next year (i.e., pushing the peak to after day 365 of the simulation with the start of the simulation on 15 February 2020, the date we assumed that the infection spread began)

Intervention settings	Assumed basic reproduction number		
	$R_0=1.5$	$R_0=2.5$	$R_0=3.5$
Intensity and length of “general contact reduction” starting on day 5 of the simulation			
Level of general contact reduction for 6 months needed to push the epidemic into the next year	>27%	Not possible	Not possible
– for 9 month intervention period (274 days)	>14%	>65%	Not possible
– for rest of the simulated year	>11%	>46%	>61%
Proportion of cases in hospital isolation (with home isolation at 50% effectiveness when hospital capacity is exceeded; beginning on day 5 of the simulation)			
Probability of case isolation in hospital needed to push the epidemic into the next year (for a 6 month intervention period)	>41%	Not possible	Not possible
– for 9 month intervention period (274 days)	>21%	>98%	Not possible
– for rest of the simulated year	>18%	>78%	Not possible

Figure 1: Numbers of prevalent symptomatic COVID-19 cases by day for the $R_0 = 1.5$, 2.5, and 3.5 scenarios and all with 25% of “general contact reduction” as modelled using CovidSIM (unrecognised introduction of the infection occurs at time 0; control measures begin at day 5 and end six months later i.e., on day 189).

Figure 2: Numbers of prevalent symptomatic COVID-19 cases by day for the $R_0 = 2.5$ scenarios and different levels of general contact reduction as modelled using CovidSIM (unrecognised introduction of the infection occurs at time 0; control measures begin at day 5 and end six months later i.e., on day 189).

Table 2: Estimated health impacts from COVID-19 in a hypothetical European country of population 10 million using CovidSIM for a range of basic reproduction number (R_0) values and differing intensity of “general contact reduction” as the control measure (see Table A1 for input parameters)

Key results	$R_0=1.5^*$		$R_0=2.5$		$R_0=3.5$	
	25% control for 6 months	50% control for 6 months	25% control for 6 months	50% control for 6 months	25% control for 6 months	50% control for 6 months
General pattern seen for symptomatic cases	Peak late in the year	Peak in next year	1 peak after intervention period	1 peak after intervention period	1 peak in intervention period	1 peak after intervention period
Symptomatic cases (which are 67% of all infected cases)						
Total	3,327,382	2,200,102	5,415,805	6,225,554	5,521,618	6,272,963
Proportion of population (%)**	33.3%	22.0%	54.2%	62.3%	55.2%	62.7%
Peak week for incidence	52	Next year	32	40	17	32
Peak month for incidence	12	Next year	7	9	4	7
Number of sick people on the worst day of the simulated year	851,592	766,739	555,676	1,743,927	1,256,488	1,494,048
Proportion of population sick on the worst day (%)**	8.5%	7.7%	5.6%	17.4%	12.6%	14.9%
Consultations (40% of symptomatic cases seek consultations, possibly mainly telephone/internet)						
Total	1,330,953	880,041	2,166,322	2,490,222	2,208,647	2,509,185
Proportion of population (%)**	13.3%	8.8%	21.7%	24.9%	22.1%	25.1%
Severe cases likely to require hospitalisation (1.0% of symptomatic cases)						
Total	33,274	22,001	54,158	62,256	55,216	62,730
Proportion of population (%)**	0.3%	0.2%	0.5%	0.6%	0.6%	0.6%
Number of people in hospital on the worst day (if capacity existed)	8,516	7,667	5,557	17,439	12,565	14,940
Proportion of population in hospital on the worst day (%)**	0.09%	0.08%	0.06%	0.17%	0.13%	0.15%
Cases likely to require ICU (25% of hospitalised cases)						
Total	8,318	5,500	13,540	15,564	13,804	15,682
People in ICU on the peak day (if capacities exist)	2,129	1,917	1,389	4,360	3,141	3,735
Cases likely to require ventilation in ICU (50% of those in ICU)						
Total**	4,159	2,750	6,770	7,782	6,902	7,841
Deaths (case fatality risk amongst symptomatic cases of 0.45%)						
Total	11,194	6,450	24,365	28,014	24,847	28,228
Proportion of population (%)**	0.11%	0.07%	0.24%	0.28%	0.25%	0.28%

* Results for $R_0=1.5$ scenarios are shaded as they were both right truncated (i.e., only the results for the first 365 days of the simulation are reported) as the epidemic peak was pushed into either very late in the year (for 25% reduction) or the following year (for 50% reduction).

** Results in these rows were not standard outputs for the CovidSIM model but were based on further Excel-based calculations from the CovidSIM output.

Appendix: Description of the CovidSIM model and model input parameters

Model dynamics

$$\begin{aligned}
 \text{Number of susceptible individuals} \quad \frac{dS}{dt} &= -\frac{S}{N} \left(\beta_P(t) \sum_{k=1}^{n_P} P_k(t) + \beta_I(t) \left(\sum_{k=1}^{n_I} I_k(t) - I_{Iso}(t) - I_{Home}(t) c_{Home} \right) + \psi \right) (1 - c_{Cont}(t)) \\
 \text{Number of individuals in the latent period} \quad \frac{dE_1}{dt} &= \frac{S}{N} \left(\beta_P(t) \sum_{k=1}^{n_P} P_k(t) + \beta_I(t) \left(\sum_{k=1}^{n_I} I_k(t) - I_{Iso}(t) - I_{Home}(t) c_{Home} \right) + \psi \right) (1 - c_{Cont}(t)) - \varepsilon E_1 \\
 \frac{dE_k}{dt} &= \varepsilon E_{k-1} - \varepsilon E_k \quad (1 < k \leq n_E) \\
 \text{Number of individuals in the prodromal period} \quad \frac{dP_1}{dt} &= \varepsilon E_{n_E} - \varphi P_1 \\
 \frac{dP_k}{dt} &= \varphi P_{k-1} - \varphi P_k \quad (1 < k \leq n_P) \\
 \text{Number of individuals in the symptomatic period} \quad \frac{dI_1}{dt} &= \pi P_{n_P} - \gamma I_1 \\
 \frac{dI_k}{dt} &= \gamma I_{k-1} - \gamma I_k \quad (1 < k \leq n_I) \\
 \text{Number of removed individuals} \quad \frac{dR}{dt} &= \gamma (1 - p_{Sick} p_{Death}) I_{n_I} \\
 \text{Number of dead individuals} \quad \frac{dD}{dt} &= p_{Sick} p_{Death} I_{n_I} \\
 \text{Number of isolated cases at time } t \quad I_{Iso}(t) &= \begin{cases} \sum_{k=1}^{n_I} p_{Sick} I_k(t) & \text{if } t_{Iso_1} \leq t \leq t_{Iso_2} \text{ and } \sum_{k=1}^{n_I} p_{Sick} I_k(t) \leq Q_{\max} \\ Q_{\max} & \text{if } t_{Iso_1} \leq t \leq t_{Iso_2} \text{ and } \sum_{k=1}^{n_I} p_{Sick} I_k(t) > Q_{\max} \\ 0 & \text{if } t < t_{Iso_1} \text{ or } t > t_{Iso_2} \end{cases}
 \end{aligned}$$

Number of fully isolated cases at time t :

$$I_{Iso}(t) = \begin{cases} \sum_{k=1}^{n_I} p_{Sick} I_k(t) & \text{if } t_{Iso_1} \leq t \leq t_{Iso_2} \text{ and } \sum_{k=1}^{n_I} p_{Sick} I_k(t) \leq Q_{\max} \\ Q_{\max} & \text{if } t_{Iso_1} \leq t \leq t_{Iso_2} \text{ and } \sum_{k=1}^{n_I} p_{Sick} I_k(t) > Q_{\max} \\ 0 & \text{if } t < t_{Iso_1} \text{ or } t > t_{Iso_2} \end{cases}$$

Number of home isolated cases at time t :

$$I_{Home}(t) = \begin{cases} \sum_{k=1}^{n_I} p_{Sick} I_k(t) - Q_{\max} & \text{if } t_{Iso_1} \leq t \leq t_{Iso_2} \text{ and } \sum_{k=1}^{n_I} p_{Sick} I_k(t) > Q_{\max} \\ 0 & \text{otherwise} \end{cases}$$

Initial values

Number of susceptible individuals	$S(0) = N - X$	
Number of individuals in the latent period	$E_1(0) = X$	
	$E_k(0) = 0$	$(1 < k \leq n_E)$
Number of individuals in the prodromal period	$P_k(0) = 0$	$(1 \leq k \leq n_P)$
Number of individuals in the symptomatic period	$I_k(0) = 0$	$(1 \leq k \leq n_I)$
Number of immune individuals	$R(0) = 0$	
Number of dead individuals	$D(0) = 0$	

Parameters

N	Population size
X	Number of initial infections
$t_{\max}$	Day after introduction of the infection when the transmission potential is highest
$Q_{\max}$	Maximum isolation capacity
t_{Iso_1}	Time at which isolation measures start
t_{Iso_2}	Time at which isolation measures end
c_{Home}	Fraction of contacts which are prevented for cases who are in home isolation
c_{Cont}	Fraction of contacts which are prevented
t_{Cont_1}	Time at which contact reduction starts
t_{Cont_2}	Time at which contact reduction ends
$c(t)$	Fraction of contacts which are reduced at time t
ψ	Force of infection which originates from outside of the population (e.g. via travellers)
R_0	Average value of the basic reproduction number
a	Amplitude of the seasonal fluctuation of R_0
D_E	Average duration of the latent period
n_E	Number of stages for the latent period
ε	Stage transition rate in the latent period ($\varepsilon = n_E / D_E$)
D_P	Average duration of the prodromal period
n_P	Number of stages for the prodromal period
φ	Stage transition rate in the prodromal period ($\varphi = n_P / D_P$)
i_P	Relative infectiousness during prodromal period
D_I	Average duration of the symptomatic period
n_I	Number of stages for the symptomatic period
γ	Stage transition rate in the symptomatic period ($\gamma = n_I / D_I$)
$\beta_I(t)$	Effective contact rate of individuals in the symptomatic period at time t $\beta_I(t) = R_0 / (i_P D_P + D_I) \cdot (1 + a \cos(t / 365))$
$\beta_P(t)$	Effective contact rate of individuals in the prodromal period at time t ($\beta_P(t) = \beta_I(t) i_P$)
p_{Sick}	Fraction of infected individuals who become sick
$p_{Consult}$	Fraction of sick individuals who seek medical help
p_{Hosp}	Fraction of sick individuals who are hospitalized
p_{ICU}	Fraction of hospitalized individuals who are admitted to the ICU
p_{Death}	Fraction of sick individuals who die from the disease

Derived variables

$$\begin{aligned}
 \text{Symptomatic cases at time } t &= p_{Sick} \sum_{k=1}^{n_I} I_k(t) \\
 \text{Asymptomatic cases at time } t &= (1 - p_{Sick}) \sum_{k=1}^{n_I} I_k(t) \\
 \text{Hospitalized cases at time } t &= p_{Sick} p_{Hosp} \sum_{k=1}^{n_I} I_k(t) \\
 \text{Cases in ICU at time } t &= p_{Sick} p_{Hosp} p_{ICU} \sum_{k=1}^{n_I} I_k(t) \\
 \text{New infections in interval } [t_1, t_2] &= \int_{t_1}^{t_2} \frac{S(t)}{N} \left(\beta_p(t) \sum_{k=1}^{n_p} P_k(t) + \beta_I(t) \sum_{k=1}^{n_I} I_k(t) \right) dt \\
 \text{New sick individuals in interval } [t_1, t_2] &= \int_{t_1}^{t_2} p_{Sick} \varphi P_{n_p}(t) dt \\
 \text{New consultations in interval } [t_1, t_2] &= \int_{t_1}^{t_2} p_{Sick} p_{Consult} \varphi P_{n_p}(t) dt \\
 \text{New hospitalizations in interval } [t_1, t_2] &= \int_{t_1}^{t_2} p_{Sick} p_{Hosp} \varphi P_{n_p}(t) dt \\
 \text{New ICU admissions in interval } [t_1, t_2] &= \int_{t_1}^{t_2} p_{Sick} p_{Hosp} p_{ICU} \varphi P_{n_p}(t) dt \\
 \text{New deaths in interval } [t_1, t_2] &= \int_{t_1}^{t_2} p_{Sick} p_{Death} \gamma I_{n_I}(t) dt
 \end{aligned}$$

Detection probability

SARS-CoV-2 infections which are brought into the country may not be detected and may spread without being noticed because the symptoms of COVID-19 may easily be confused with other influenza-like illnesses (ILI). Few practitioners may decide to order a SARS-CoV-2 test for what they regard a normal ILI patient while no community-transmitted cases in the population have been reported. If we assume that fraction of p_{Test} ILI patients who (a) seek medical help or who (b) are hospitalized or who (c) die from the disease are tested for SARS-Cov-2, then the probability that *not one single test* has been performed on a COVID-19 patient by time t despite the ongoing transmission in the population is given by:

$$(1 - p_{Test}) \int_0^t P_{nP}(\tau) \varphi_{P_{Sick}}(p_{Consult} + p_{Hosp} + p_{Death}) d\tau.$$

The probability that at least one test has been performed (and has returned a positive result) is then

$$1 - (1 - p_{Test}) \int_0^t P_{nP}(\tau) \varphi_{P_{Sick}}(p_{Consult} + p_{Hosp} + p_{Death}) d\tau.$$

Parameters used in the modelling with CovidSIM

Table A1: Input parameters for modelling the health impacts for a hypothetical European country using CovidSIM

Parameter	Value/s used	Further details
Population size	10 million	The population we selected for a hypothetical European country.
Incoming infected people from outside of the study population	10 per day (from 15 February)	We assumed that the first cases with subsequent silent transmission began on 15 February when nine European countries had cases. For the whole course of the one year simulation, we assumed an average of 10 infected people per day were arriving in the hypothetical country from other countries (e.g., by legal and/or illegal crossing of land borders).
Infections that lead to sickness	67%	This figure is still uncertain but we used the same estimate as per modelling by Imperial College at “two thirds of cases being sufficiently symptomatic to self-isolate” [3]. Of note is that another modelling study used a 50% value [15]. Nevertheless, some proportion of asymptomatic cases is consistent with the findings of a very large Chinese study [12], where 81% of cases of COVID-19 did not involve severe illness.
Sick people seek medical help (including telephone and internet consultations)	40%	We used the default value in the CovidSIM model, which is based on medical consultations for influenza-like illness (ILI). During a pandemic there might be a shift away from face-to-face consultations with health workers, so that some of these consultations may be either telephone or internet-based. This parameter is not used for determining subsequent outcomes like hospitalisations and deaths. We further assume that cases only seek medical help once.
Sick people need hospitalisation	1%	This estimate is highly uncertain. We have multiplied by 5 the percentage which has been observed for seasonal influenza in Germany (0.2%), to account for the apparent increased severity of COVID-19. The high uncertainty for this parameter is due to the likely under-diagnosis of mild cases in many settings (impacting the size of the denominator). It also may vary between countries given the use of hospital facilities to isolate mild cases. Modellers in the United Kingdom (UK) have used 4.4% (of all infected cases) [3], and for modelling in the United States 3%, 5% and 12% have been proposed [16]. The length of hospitalisation was assumed to be 10 days which is similar to other modelling work e.g., 10.4 days for the UK [3].
Hospitalised cases need intensive care (ICU admission)	25%	We used the data from a very large Chinese study for the ratio of “critical” to “severe” cases (i.e., $4.7\% / (13.8\% + 4.7\%) = 25.4\%$) [12]. This is similar to the Chinese case series reported by Wang et al. at 26.1% [17]. Nevertheless, it is higher than reported in a smaller case series from Singapore at 11% (2/18) [18]. A UK modelling study used a proportion of 30% “based on early reports from COVID-19 cases in the UK” [3].
Intensive care cases requiring mechanical ventilation	50%	We use the same value as per a US model of 50% [19] for additional calculations outside of CovidSIM. This proportion is around that reported in a Chinese study of 47% (17/36 ICU admissions) [17] but is less than in another Chinese study at 71% (37/52) [20].
Sick people die from the disease (case fatality risk)	0.45%	Given the relatively high quality of the healthcare systems in Europe, we considered the lower end of the range reported by the WHO for the infection fatality risk (IFR) of 0.3% to 1% (based on 3 publications) [21]. This IFR was then adjusted by the proportion assumed to be symptomatic (at 67%, as above) to give a case fatality risk (CFR) of 0.45% (i.e., $0.3\% \times 100\% / 67\% = 0.45\%$). Nevertheless, we note that higher estimates exist, including a CFR for “China outside of Hubei Province” of 0.81% (95%CI: 0.67 to 0.98; and adjusted for the time delay in reporting deaths) [22]. Another CFR for “China outside of Hubei Province” was similar, at 0.9% (95% credible interval: 0.6-1.3%; also adjusted for the time delay in reporting deaths) [23]. A value

Parameter	Value/s used	Further details
		used in UK modelling was an IFR of 0.9% [3].
Basic reproduction number (R_0)	1.5, 2.5 and 3.5 (3 scenario analyses)	On 6 March 2020, the WHO reported that this number was likely to be in the range of 2.0 to 2.5 [24]. But given persisting uncertainty, we used the same three values as in the modelling work by Hellewell et al [2]. Of note is that an earlier review of 12 studies [25], suggested estimates that ranged from 1.4 to 6.49, with a mean of 3.28, a median of 2.79 and interquartile range of 1.16. But this review also noted that in more recent studies, R_0 estimates seem to have stabilised at around 2–3. Recent UK modelling used an estimate of 2.4 (range: 2.0 to 2.6) [3].
Relative contagiousness in the prodromal period	50%	There is uncertainty around this value but we used the same estimate as in recent UK modelling [3]. This has biological plausibility as while there is similarity in viral loads between asymptomatic and symptomatic COVID-19 patients [26], it would be expected that those who are fully symptomatic (with a cough etc.) would be more likely to transmit infection. Of note is an estimate from the Diamond Princess cruise ship outbreak, that 17.9% of COVID-19 infections were from asymptomatic individuals (95% credible interval 15.5-20.2%) [27]. But it is unclear how generalisable this finding is given the crowded cruise ship conditions and the typically elderly nature of the passengers.
Latency period	4 days	We used an average duration of 4 days as per Read et al [28], with a standard deviation of 25% (calculated using 16 stages; Erlang distribution). This is similar to the estimate in a Chinese study which reported a median latent period of 3.69 days [29].
Prodromal period	1 day	There is as yet insufficient data on this for COVID-19, so we used an assumed value for influenza (SD = 25%, Erlang distribution).
Symptomatic period	10 days	The WHO-China Joint Mission report stated that “the median time from onset to clinical recovery for mild cases is approximately 2 weeks and is 3-6 weeks for patients with severe or critical disease” [8]. But given that mild cases may have been missed in this particular assessment, we used a slightly shorter time period of 10 days (SD = 25%, Erlang distribution). During this symptomatic period, cases were considered infectious. We note that there is evidence from COVID-19 cases of shedding of viral RNA from sputum that has outlasted the end of symptoms [30]. However, the significance of this for disease transmission is unknown.
Interventions		
General contact reduction	Two scenarios (25%, 50%) and threshold analyses	<p>This variable covers the summated impact of a potentially wide variety of different interventions: people may adopt enhanced personal hygiene measures (hand washing, cough etiquette etc.); they may decide to have fewer contacts (physical distancing); and governments may close venues and schools, restrict mass transit, curtail mass gatherings, and restrict travel (within and between countries).</p> <p>Scenario “25%”: This scenario is our approximation of a modest level of the above listed interventions.</p> <p>Scenario “50%”: This scenario assumed an intensification of the measures being adopted (relative to the above scenario).</p> <p>Threshold analyses: This was where we increased the level of “general contact reduction” to a level which pushes the epidemic peak into the following year (i.e., past day 365 after the first introduction of the infection into the country).</p>
Contact reduction begins	19 February 2020	This date is somewhat arbitrary but does represent a time of increased awareness of the disease in Europe as there were 9 European countries having reported cases to WHO and one reporting a death (in France). It is equivalent to day 5 of the simulated year.

Parameter	Value/s used	Further details
Contact reduction duration	6 months (9 months and “rest of year” in scenario analyses)	This period was arbitrary and was varied in threshold analyses (Table 1). As further discussed in the main text the feasibility of such sustained interventions for any country is highly uncertain and may not be realistic given the adverse social and economic implications.
Seasonality effect	Variation in R_0 of 25%	Winter conditions are known to accelerate transmission of influenza and also the other coronaviruses which cause common cold like symptoms [31]. Enveloped viruses show strong seasonality with winter peaks [32], and SARS-Cov-2 is an enveloped virus. Even though there are many uncertainties relating to seasonality and this novel coronavirus [33], it seems prudent to assume some seasonal fluctuation so we increased the average by 25% in winter and reduced it by 25% in summer (with a sinusoidal variation throughout the simulated year), using a mid-winter peak for Europe of 15 January (i.e., day 334 of the simulation).
Case isolation (only used in the threshold analyses)	Varied in threshold analyses (Table 1)	<p>We set the following values in threshold analyses (while setting 0% for “general contact reduction” – see above):</p> <ul style="list-style-type: none"> • Probability that a sick person is isolated = varied in threshold analyses • Maximum capacity of isolation wards = 4 per 10,000 population (i.e., see below). • Contact reduction for cases in home isolation = 50% (this occurs while hospital isolation capacity is exceeded) • Beginning of case isolation measures = the 19 February date as above (i.e., assuming increased clinician awareness from cases in nine European countries at this time). • Duration of case isolation measures = 6 months (183 days), or 9 months (274 days) or the rest of the simulated year. <p>For isolation capacity in hospitals we assumed that 10% of hospital beds could be converted for this use during the pandemic, with the country having a total of 44,000 hospital beds; or 44 per 10,000 population. For this we used the median hospital beds per 1,000 population for 12 European states in the OECD and in the 5 to 15 million range for total population size, i.e., using data from: Austria, Belgium, Czechia, Denmark, Greece, Hungary, Norway, Portugal, Slovakia, Sweden and Switzerland [34]. If 10% of these hospital beds were used for isolation purposes, then this is 4 beds per 10,000 population for use in the modelling process, or 4,000 in total in the country.</p>
