Abstract

Background The 2019 coronavirus disease (COVID-19) represents a significant public health threat g lobally. Here we describe efforts to compare epidemic growth, size and peaking time for countries in Asia, Europe, North America, South America and Australia in the early epidemic phase.

Methods Using the time series of cases reported from January 20, 2020 to February 13, 2020 and transportation data from December 1, 2019 to January 23, 2020 we have built a novel time-varying growth model to predict the epidemic trend in China. We extended our method, using cases reported from January 26, 2020 - or the date of the earliest case reported, to April 9, 2020 to predict future epidemic trend and size in 41 countries. We estimated the impact of control measures on the epidemic trend.

Results Our time-varying growth model yielded high concordance in the predicted epidemic size and trend with the observed figures in C hina. Among the other 41 countries, the peak time has been observed in 28 countries before or around April 9, 2020; the peak date and epidemic size were highly consistent with our estimates. We predicted the remaining countries would peak in April or May 2020, except India in July and Pakistan in August. The epidemic trajectory would reach the plateau in May or June for the majority of countries in the current wave. Countries that could emerge to be new epidemic centers are India, Pakistan, Brazil, Mexico, and Russia with a prediction of 10^5 cases for these countries. The effective reproduction

> number R_t displayed a downward trend with time across countries, revealing the impact of the intervention remeasures i.e. social distancing. R_t remained the highest in the UK (median 2.62) and the US (median 2.19) in the fourth week after the epidemic onset.

> **Conclusions** New epidemic centers are expected to continue to emerge across the whole world. Greater challenges such as those in the healthcare system would be faced by developing countries in hotspots. A domestic approach to curb the pandemic must align with joint international efforts to effectively control the spread of COVID-19. Our model promotes a reliable transmissibility characterization and epidemic forecasting using the incidence of cases in the early epidemic phase.

1 1. Introduction

epicenters.

21

In early December 2019, a novel severe acute respiratory syndrome coronavirus, SARS-COV-2, emerged into the human population in Wuhan, China¹⁻⁷ 3 The first coronavirus disease 2019 (COVID-19) case outside China was reported on January 13, 2020 in Thailand. In just several weeks, the local trans-5 mission started rapidly in a broad array of countries in Asia, Europe, North America, South America and Australia, with the emergence of new epicenters of spread, such as the US, Italy, Spain, and France (https://www.who.int). The rapid spreading of SARS-COV-2 has led to a major global public health 9 threat. The World Health Organization (WHO) declared the spread of 10 COVID-19 a pandemic on March 11, 2020. 11 Early epidemic forecasts consisting of the likely trajectory of an unfolding 12 outbreak can help guide the type and intensity of interventions $^{8-10}$. The vast 13 majority of these approaches considered early exponential growth dynamics, 14 an assumption that could lead to substantial overestimation of epidemic size 15 and peak timing. To enhance the ability to forecast epidemics, it is crucial to 16 characterize the shape of epidemic growth and accurately assess early trends 17 of sub-exponential growth phenomenon 1^{1-13} . Currently, the global case count 18 continues to rise, but there is a limited understanding of the extent of the 19 outbreak and epidemic growth profile, particularly for the new emerging 20

2

In this study, we attempt to assess and compare the extent of the out-22 break across countries, draw preliminary conclusions about the impact of 23 control measures, and characterize real-time effective reproduction number 24 R_t . Our model, without making explicit assumptions about the epidemic 25 growth profile, is a generalizable framework to estimate the early dynamic 26 trends of COVID-19 from the incidences of cases. We estimated the epidemic 27 trend and size in China using the cases reported from January 20, 2020 to 28 February 13, 2020, and in other 41 countries using data from January 26, 29 2020, - or the date of the earliest case reported, to April 9, 2020. 30

31 2. Methods

32 2.1. Sources of Data

We obtained the number of COVID-19 confirmed cases of time series 33 data between January 20, 2020 to February 13, 2020 in China from the 34 official websites of the National Health Commission of China and Provincial 35 Health Committees (http://www.nhc.gov.cn). The data of cases for each 36 of the 29 provinces (25 provinces plus 4 municipalities including Beijing, 37 Shanghai, Chongqing and Tianjin) at 23 time points were included, as well 38 as for Wuhan and major cities in Hubei. The start date of January 20 was 30 chosen because the official diagnostic protocol released by WHO on January 40 17 allows the new COVID-19 cases to be diagnosed accurately and rapidly. 41 All cases were laboratory-confirmed with the detection of viral nucleic acid 42 following the case definition by the National Health Commission of China. 43

Wuhan is connected to other cities in China via high-speed railway, high-44 way, and airplane flights. Population mobility statistics to estimate the ex-45 posed sizes in cities outside Wuhan were based on transport-related databases 46 below: 1) Railway and airline travel data: the daily numbers of outbound 47 high-speed trains from Wuhan with corresponding travelling hours were ob-48 tained from the high-speed rail network (http://shike.gaotie.cn) from Decem-49 ber 1, 2019 to January 23, 2020, and similarly daily numbers of outbound 50 flight and hours for air transport were obtained from the Citytrip network 51 (https://www.ctrip.com) from December 1, 2019 to January 23, 2020. We 52 calculated daily travelling hours which equal to the product of the outbound 53 trip counts and the travelling hours for rail and air transport respectively 54 from Wuhan to each major city. For a given province, we summarized the 55 total number of travelling hours across all cities in that province. 2) Highway 56 mileage data: we collected highway mileage data from bus station networks at 57

https://www.gichezhan.cn. It contains the highway mileage from Wuhan to 58 16 cities in the Hubei Province. 3) Migration data: we obtained population 59 migration data from the Baidu Migration Map (http://qianxi.baidu.com) 60 which includes both the percentages and volumes of migration from Wuhan 61 to other cities and provinces from January 1 to 28, 2020. Total travelling 62 hours for rail and air flight, and migration scales are plotted by the province in 63 Supplementary Figure 1. Accumulated time on trains, on airplanes, highway 64 mileage and population migration scales were used to model the underlying 65 epidemic sizes in the provinces or cities outside Wuhan at the time 0 of this 66 study which is on January 20, 2020. 67

From Supplementary Figure 1, we observed that Guangdong has the 68 largest traveling hours through railway and airplane outbound from Wuhan 69 among the provinces. Also, the largest population has immigrated from 70 Wuhan to Henan. In Hubei province, Cities of Huanggang and Xiaogan are 71 the closest to Wuhan in terms of mileage and the scale of migration. These 72 simple observations are consistent with our result that Guangdong, Henan, 73 Huanggang and Xiaogan have the largest number of estimated primary in-74 fected cases imported from Wuhan on January 20, 2020. 75

We obtained the number of COVID-19 confirmed cases in 41 countries using data from January 23, 2020, or the date of the earliest case reported, to April 9, 2020 from the offical websites of WHO at https://www.who.int. We included 41 countries with at least confirmed cases on April 9 2020 in five continents: Asia, Europe, North America, South America, and Australia.

81 2.2. Modelling the transmissibility of COVID-19

We introduce the main notation here. All times are calendar times, measured in days since the start of the epidemic.

Y_{kt}	number of accumulated diagnosed case till day t ,
TR_k	daily traveling hours on trains from Wuhan,
FL_k	daily traveling hours on airplane from Wuhan,
RM_k	highway mileage from Wuhan,
MI_k	volumes of migration from Wuhan from January 1 to 28, 2020
α_k	number of underlying primary infected cases,
W_{kt}	underline number of infected individuals who are infectious,
m	duration of infectious period (day),

where the subscript k represents country, province or city k, the subscript t 84 represents day t. TR_k and FL_k are constructed based on the two reasons. 85 One is that the longer people stay on the train or plane, the more likely 86 he(she) is to get infected. Another is that the infection happens in local 87 area, hence the number of trains or planes has more information than the 88 population taking trains or planes. In addition, in Hubei province, most 89 people left Wuhan by cars, we use RM_k as one of measurement for the spatial 90 distance between city k and Wuhan. 91

⁹² 2.2.1. Modeling for 28 provinces

First, we build an index α_k to represent the baseline infected cases in province k on 20 January, 2020. Particularly, we will use TR_k , FL_k and MI_k to measure the relationship between provice k and Wuhan. We suppose

$$\alpha_k = \beta_1 \times TR_k + \beta_2 \times FL_k + \beta_3 \times MI_k, \text{ for province } k, \qquad (1)$$

where $\beta = (\beta_1, \beta_2, \beta_3)'$ are estimated by the observed Y_{kt} in provinces $k = 1, \dots, K$ and $t = 1, \dots, T$.

So far, we are not sure the key epidemiological parameters that affected spread and persistence. We hence make assumptions as least as possible. It is obvious that the average cases in province k diagnosed at day t is proportional to the scale of infectious cases on day t-1, $W_{k,t-1}$. We then assume a Poisson distribution for the new cases diagnosed in province k at day t with mean $\gamma_{kt}W_{k,t-1}$, that is

$$dY_{kt} = Y_{kt} - Y_{k,t-1} \sim Possion(\gamma_{kt}W_{k,t-1}), \tag{2}$$

104 where ' \sim ' means 'distributed as'.

¹⁰⁵ Under the unified leadership of the central government, we suppose the ¹⁰⁶ trend of γ_{kt} over day t is the same for 28 provinces, that is, $\eta_{kt} = \eta_t$ is ¹⁰⁷ independent of k so that

$$\gamma_{kt} = \eta_t \times \gamma_{k,t-1}.\tag{3}$$

To avoid strong assumptions about the evolution of the epidemic, we allow η_t to be arbitray function of t. We determine the functional form of η_t by pointwise estimating η_t and checking the resulting pattern over t. Denote the resulting functional form for η_t by $\eta_t = \eta_t(a)$.

The new cases diagnosed at day t may be not reported fully. That is,

 $E(dY_{kt}) = pdW_{kt}$ and p < 1. The estimation for p need more information except that we have. Fortunately, simple mathematical derivation shows that the value of p may influence the prediction of the absolute epidemic size but will not affect the trend of the epidimic, for example, the reproduction number, the duration and the peak time of the epidemic and relative epidemic size, in which we are interested. Hence, we suppose p = 1 in the paper. Since

$$W_{kt} = W_{k,t-1} + dW_{kt}, \ dW_{kt} = E(dY_{kt}) = \gamma_{kt}W_{k,t-1}.$$
(4)

With the chain calculation, we have $dW_{kt} = \gamma_{kt} \prod_{j=0}^{t-1} (\gamma_{kj} + 1) W_{k0}$ and $W_{kt} = \prod_{j=0}^{t-1} (\gamma_{kj} + 1) W_{k0}$, where $W_{k0} = \alpha_k$ and $\gamma_{k0} = 0$. In practice, the infected patients will be isolated and removed from the infectious source. With the notation m of duration of infectious period, we hence have

$$W_{kt} = \prod_{j=0}^{t-1} (\gamma_{kj} + 1)\alpha_k - I(t > m) \prod_{j=0}^{t-(m+1)} (\gamma_{kj} + 1)\alpha_k.$$
(5)

Denote $\gamma_1 = (\gamma_{11}, \dots, \gamma_{K1})'$ and all of the parameters by $\delta = (\gamma'_1, a', \beta')'$. Taken (1), (2), (3) and (5) together, the loglikelihood function was

$$L(\delta) = \sum_{k=1}^{K} \sum_{t=1}^{T} \{ dY_{kt} \log(\lambda_{kt}) - \lambda_{kt} \} + C$$

=
$$\sum_{k=1}^{K} \sum_{t=1}^{T} \left(dY_{kt} \log[\gamma_{kt} X_{k}^{T} \beta \{ \Pi_{i=1}^{t-1} (1 + \gamma_{ki}) - I(t > m) \Pi_{i=1}^{t-m} (1 + \gamma_{ki}) \} \right]$$

-
$$\gamma_{kt} X_{k}^{T} \beta \{ \Pi_{i=1}^{t-1} (1 + \gamma_{ki}) - I(t > m) \Pi_{i=1}^{t-m} (1 + \gamma_{ki}) \} + C, \qquad (6)$$

where C is a constant independent of δ , m is determined by minimizing the prediction error. The confidence intervals were obtained based on 200 bootstrap resampling^{14, 15}.

¹²⁸ 2.2.2. Modeling for Hubei, Wuhan and the other countries

The modeling and the loglikelihood function for Hubei are similar with those for 28 provinces except that FL_k is replaced by RM_k and provinces are replaced by cities, because there are not flights between the cities in Hubei and Wuhan, and the most people leave Wuhan by cars or buses. Specifically,

$$\alpha_k = \beta_1 \times TR_k + \beta_2 \times RM_k + \beta_3 \times MI_k, \text{ for city } k \text{ in Hubei.}$$
(7)

The modeling and the likelihood function for Wuhan and countries, including Singapore, South Korea, Japan, Italy, German, Span, France and Iran, are similar with those for 28 provinces except that α_k is directly estimated by the diagnosed cases in Wuhan and other 41 countries respectively.

¹³⁷ 2.2.3. The calculation of the time-dependent reproduction number R_t

The equation $dW_{kt} = \gamma_{kt}W_{k,t-1}$ implies that, when $W_{k,t-1} = 1$, we have $\gamma_{kt} = dW_{kt}$. Hence γ_{kt} is the average number of new infections created by an infectious individual in one day, then $\phi_t = \sum_{k=1}^{K} \gamma_{kt}/K$ is the corresponding average number across provinces or cities. Since one infectious individual can make infection for m days, an infectious individual then can lead to $R_t = m\phi_t$ new infections, which indeed is the time-dependent reproduction number^{16, 17}.

2.2.4. Predication of potential peak time and turning point in COVID-19 outbreak

With the estimated parameters by maximizing the loglikehood (6), we 147 can estimate and predict the average new cases $dW_{kt} = \gamma_{kt} \prod_{j=0}^{t-1} (\gamma_{kj} + 1) \alpha_k$, 148 then the cumulative cases $\tilde{W}_{kt} = \prod_{j=0}^{t} (\gamma_{kj} + 1) \alpha_k$. Based on the new cases 149 and cumulative cases, we can predict the peak time and the turning point in 150 the COVID-19 outbreak. In the paper, we defined the peak time to be the 151 day at which the incidence cases began to decline, and the turning point to 152 be the day when the number of the cumulative cases reached a plateau, which 153 satisfying $|\partial f(v)/\partial v| \leq c_0$, where $f(v) = \frac{\partial \tilde{W}_{kt}/\partial t|t=v}{\partial \tilde{W}_{kt}/\partial t|t=v-1}$ and c_0 is a prespecified 154 small number. We take $c_0 = 2e - 03$ through the analysis. 155

156 3. Results

157 3.1. Fitting a generalized growth model using a time-series data

We fit the time-varying generalized growth model using the early stage 158 outbreak series data for Wuhan, Hubei province, China, and other 41 coun-159 tries with at least 2,000 confirmed cases on the date of April 9 2020. The 160 optimal fitted model for each country or region was chosen based on the 161 prediction error of the lowest values (Supplementary Figures 2 to 4). The 162 corresponding empirical distributions of the parameters are shown in Table 163 1. The parameter m, the estimated mean infectious duration, ranged from 4 164 to 13 days, with the highest value of 13 for the epidemic in Italy. The short 165

duration of 4 days was estimated for South Korea. The value of m reflects 166 the duration of infectious period, which in practice could be intervened by 167 control measures such as early diagnosis and isolation. Another parameter 168 $\eta(t)$ quantifies how rapidly the growth rate $\gamma(t)$ at time t changed; the func-169 tional form of $\eta(t)$ was estimated by pointwise estimation using data till t for 170 each model respectively. The growth rates declined most rapidly in China 171 and Thailand (median η : 0.86 to 0.89), and most slowly in India, Mexico, 172 Singapore and Sweden (median η : 0.98 to 0.99). 173

174 3.2. Predictive performance of model fitting

Using the calibrated model based on m and the form of $\eta(t)$, we esti-175 mated the real-time growth rates based on the number of confirmed cases at 176 $t = 1, \ldots, T$ by maximizing the likelihood function displayed in the Method 177 section. The underlying growth process was lower than the constant expo-178 nential growth rate as medium $\eta(t)$ was consistently estimated at less than 179 1(Supplementary figure 3), similar to findings of sub-exponential growth dy-180 namics for epidemics of influenza, Ebola etc with the deceleration growth 181 factor below 1 $^{18, 19}$. 182

For China, we used case incidence data from January 20 to February 13 183 as the epidemic reporting period to fit the model for trajectory predictions. 184 The observed values fall within 95% CI of the prediction band in general, 185 suggesting a good model fitting (Figure 1 and Supplementary Figures 8-9). 186 We predicted that the epidemics would fade out around February 19 to 24 187 across the 28 provinces, about 4 weeks after the intervention starting from 188 January 20; this is in concordance with the actual timing in which no more 189 new cases were observed at the end of February (http://www.nhc.gov.cn). 190 For 28 provinces in China, the estimated size was at 8553 to 9460 and 11,000 191 to 12,600 for Hubei province; both 95% CI estimates cover the observed 192 figures (Table 2). For Wuhan, due to the changes in the diagnosis criteria, 193 the predicted number of cases was not comparable after February 13. We 194 estimated the epidemic would fade out around the end of February, which is 195 close to the final date in which no more new cases were observed in Wuhan. 196 Within each province, the observed final epidemic size was within the 95%197 CIs of prediction except 5 provinces, yet the prediction was still within 10%198 +/- flanking the upper or lower bound (Supplementary Table 1). Given the 199 intervention measures are similar across provinces in China besides Hubei, 200 it is not surprising that we observed the trend that the provinces with a 201 higher estimated risk of imported cases alpha from Wuhan had an increased 202

epidemic size. However, there were some exceptions. For example, Bei-203 jing ($\alpha = 28;95\% CI: 7-49$) and Shanghai ($\alpha = 16; 4-28$) were in the 204 high-risk group but the final infection numbers were 286 and 261. On the 205 contrary. Heilongjiang was in the low-risk group ($\alpha = 4: 1-6$) whereas the 206 final infections were at 252. This implies the stronger intervention locally or 207 compliance in densely populated municipalities (Beijing or Shanghai), than 208 that in Heilongjiang, the north-east region far away from Wuhan. Over-209 all our time-varying growth model provides a good fitting using time-series 210 confirmed cases for the epidemic of COVID-19 in China. 211

212 3.3. Projection of the epidemic and final size in 41 countries

We projected the future growth trajectory underlying the outbreak using 213 the daily confirmed case data from January 23, 2020 - or the date of the 214 earliest case reported - to April 9, 2020 in 42 countries across Asia, Europe, 215 North America, South America and Australia. Our prediction is based on the 216 estimated parameters assuming the sustainability of intervention measures. 217 The time-varying growth model fitting to the time-series data performed 218 well as shown by the observed cases generally falling in the 95% CI of the 219 prediction bound in each plot (Figure 1 and Supplementary Figures 8-12), 220 except for South Korea in the very early phase. The predicted cases were 221 higher than the observed number of infections from February 8 to 25, likely 222 due to a proportion of infections being greatly understated - the hiding cases 223 from the religious group. 224

We predicted the epidemic size and duration of the outbreak with the 225 assumption of current model fitting parameters (Table 2). In Asia, the epi-226 demic will continue until May in Philippine, Malaysia and Iran, and July in 227 Indonesia. Strikingly, the epidemic would have the longest outbreak spread 228 until February or March 2021 in Indian and Pakistan, with the final infec-229 tions at more than a million. For Japan and Singapore, we were not able 230 to do predictions on the epidemic sizes and duration because the estimated 231 time-varying growth rates kept on increasing at the end of the study period 232 - which is concordant to the big daily jump in cases observed in these two 233 countries recently; thus incidence case data in a longer period are required for 234 valid predictions using our model. In Europe, the epidemic will not fade out 235 until May or June for the majority of countries. However the epidemic may 236 last until August (Russia and Sweden). In North America, the epidemic will 237 continue until May (Canada, Dominican Republic), June (US) and October 238 (Mexico), and the infection are estimated to be around 1 million in the US, 230

and 10⁵ in Mexico. In South America, the epidemic will continue until May
(Chile) and June (Brazil, Colombia and Panama). Among them, Brazil has
the largest estimated infections with more than 10⁵.

243 3.4. Estimation of peak time

We estimated the peak time, the day at which the incidence cases began 244 to decline based on the estimated daily cases dW_{kt} (see Methods). Among 41 245 countries, the peak time has been observed in 28 countries before or around 246 April 9, 2020 (Table 3 & Supplementary Figures 13-15). The estimations 247 in the above countries are concordant to the observed period during which 248 incidence cases declined. For other countries, under the current parameters 249 with continuity of intervention measures, we estimated the epidemic would 250 peak in April or May 2020 for the majority of countries, except for India 251 (July) and Pakistan (August). The predicted numbers of accumulated cases 252 at the peak point were also consistent with the observed figures. Based on 253 the predicted number of infections, we estimated the maximum number of 254 ventilators for the peak requirement. For example, at least 500,000 venti-255 lators need to be prepared for the epidemic peak in India, $\sim 100,000$ for 256 Pakistan. Considering the death or recovery rate, the number is regarded as 257 the upper bound in practice. 258

259 3.5. Impact of the reduction of the infectious period

Shortening the time from the infection onset (symptomatic or asymp-260 tomatic) to isolation, termed as 'infectious period' in this paper, is vital as 261 it will reduce transmission. The control strategies could rely on social dis-262 tancing, earlier isolation of cases and population-based testing to identify 263 the presymptomatic or asymptomatic cases. Here we evaluated the impact 264 of shortening the infectious period on the epidemics, showings the epidemic 265 curve for each country, assumed to be 1 or 2 days shorter in the duration 266 of infectivity infectious period (Supplementary Figures 13-15). A reduction 267 of the infectious period by 1 or 2 days would have a negligible effect on the 268 peak time, as the estimation was essentially the same. The reduction of the 269 infectious period by 1 or 2 days would lead to a significantly flatted epidemic 270 curve across all the countries. For example, the 2-days decrease in the in-271 fectious period would result in a significant reduction of the final epidemic 272 size in India (31.1%), Pakistan (39.3%), Russia (22.6%), Brazil (26.8%), and 273 Mexico(18.0%).274

275 3.6. Estimation of real-time effective reproduction number R_t

We quantified the real-time reproduction number R_t (see Method sec-276 tion)^{17, 20, 21}, based on the estimation parameters of growth rates γ and the 277 infectious period m. The R_t exhibited a declining trend with time and vari-278 ability in the estimates across countries (Table 4). The uncertainty of Rt 279 was largest in the first week and gradually became smaller with time (Table 280 4). In the first week, 28 countries displayed R_t below 5 while 14 exhibited 281 large R_t above 5. Italy and Spain displayed the highest R_t at 12.36, and 9.26 282 respectively. R_t estimations become closer ranging from 0.95 (Singapore) 283 to 5.54 (Spain) in the second week. During the first month of the epidemic 284 period, all countries displayed a declined trend towards 1 in the epidemic pe-285 riod with varying deceleration rates, revealing the impacts of the intervention 286 strategies. In the fourth week, 14 countries exhibited R_t below 1, the highest 287 in UK (2.62) and the US (2.19). For Singapore and Japan, although both 288 displayed the declining trend in the first month, there is an inclining trend 289 starting from April, implying the intervention could not be effective in the 290 late stage (Supplementary Figure 16). R_t displayed the fastest deceleration 291 in China with the most pronounced changes during the third to fourth weeks; 292 this may reveal the significant impact of intervention measures implemented 293 since January 20, 2020 in the first week. 294

Table 1: Summary of fitting parameters for the selected model in 10 countries in 2020.

	Epidemic study period	m	Medium η_t (95%)	form of η_t
Asia				
China	01/20 - 02/13	6	0.89(0.87, 0.91)	$a_0 + a_1(t - t_1) - a_2(t - t_2)$
Hubei Province, China	01/20 - 02/13	9	0.86(0.84, 0.88)	$a_0 + a_1(t - t_1) - a_2(t - t_2)$
Wuhan, China	01/20 - 02/13	6	0.88(0.86, 0.90)	$a_0 + a_1(t - t_1) - + a_2(t - t_2)$
India	03/04-04/09	9	0.99(0.98, 1.00)	$a_0 + a_1(t - t_1)_{-}$
Indonesia	03/08-04/09	10	0.97(0.96, 0.98)	$a_0 + a_1(t - t_1)_{-}$
Iran	03/19-04/09	8	0.96(0.96, 0.98)	$a_0 + a_1(t - t_1)$
Japan	$\frac{02}{14} - \frac{04}{09}$	8	0.97(0.96, 0.98)	$a_0 + a_1(t - t_1)$
	0_/ 0 _ / 00		,,	$a_0 + a_1(t - t_1)I(t_1 \le t \le t_2)$
South Korea	01/24 - 04/09	4	0.93(0.92, 0.94)	$+a_1(t_2 - t_1)I(t_1 \leq t \leq t_2)$ $+a_1(t_2 - t_1)I(t > t_2)$
Malaysia	02/27-04/09	11	0.94(0.93, 0.95)	$a_0 + a_1(t - t_1) - + a_2(t - t_2)$

Table 2: Estimation of median growth rate, final epidemic size and ending date for each country

The ending date is the day when the number of the cumulative cases reach a plateau (see Methods). For Japan and Singapore, the predicted trend does not reach a plateau because of increasing growth rate at last time points (Supplementary Figure 3(h) & 4(h))

Figure 1: The estimated (red-solid) and observed (black-dotted) cumulative number of infectious over time t, as well as 95% CI (red-dashed) of the estimators. In addition, the green dots in the plot for Beijing and Guangdong in China refer to the number of reported cases which were not included for the model fitting.

Table 3: The predicted or observed peak date and the corresponding cumulated size among the different countries

^{*} Peak date has been observed. Due to the fluctuation of the daily reported cases, the observed peak interval was listed in stead of the exact peak date.

The number of maximum cases at the peak is the accumulated number of cases at the peak period. The number of ventilator for the peak requirement is calculated based on the predicted infection. We

assume 5 - 10% of the infected patients need the ventilator²².

Table 4: Estimated Medium R_t (95%CI) in the subsequent week

Figure 2: The proportion of epidemic size when the duration of infectious period m is reduced by 1 and 2. The reduction of infectious duration refers to shorten the time from the infection onset (symptomatic or asymptomatic) to isolation by intervention measures.

295 4. Discussions

Here we predicted that the COVID-19 pandemic will persistently spread 296 over many countries and will last on average 5 to 6 months since January 2020 297 for the current wave. We estimated, given no further intervention measures, 298 that India would emerge to be a new epidemic center, as well as Pakistan, 299 Brazil, Russia and Mexico. Effective intervention measures by reducing the 300 infectious period would result in an 50% reduction in the final epidemic sizes. 301 R_t had a declining trend in almost all countries, revealing the impact of the 302 intervention measures i.e. social distancing. 303

Our real-time estimation framework can yield a reliable prediction of 304 the final epidemic size using the data from the early phase of the epidemic. 305 We evaluated the performance of our model using incident case data from 306 January 20 to February 13, 2020 in China. We predicted the epidemic would 307 fade out on February 19 to 24 across 28 provinces in China with a one-308 week lag in Wuhan; the epidemic size was estimated at 8,500 to 9,500, and 309 11,000 to 12,600 in 28 provinces and Hubei respectively. The outbreak size 310 and epidemic duration estimated are found to be highly consistent with the 311

observed figures (https://www.who.int). The prediction of the final epidemic size based on the model that assumes early exponential growth could tend to overestimate the epidemic size, which has been shown in the previous studies^{10, 23-28}.

We estimated that the most affected countries in the next wave of the 316 pandemic will be India, Pakistan, Brazil, Mexico as well as Russia. All 317 these countries are currently undergoing regional or national lockdown except 318 Mexico. Given that thousands of ventilators are needed for the peak around 319 May to July, it is immediately important for these countries to prepare the 320 ICU beds. In Europe, most countries have peaked in the curve, and the final 321 outbreak size was estimated to exceed 10^5 in Italy, France, UK, Germany 322 and Spain. For the United States, the estimated final epidemic size will 323 surpass 1 million, peaking around July 2020. A recent report calculated that 324 81% of British and the United States populations would be infected, with 325 approximately a half and 2.2 million deaths respectively²⁹. The high value is 326 based on the assumption of R_0 at 2.4, while our results demonstrate that real-327 time R_t decelerated under interventions. Thus, their estimates are likely to be 328 the higher bound of the true value. In Asia, besides China, South Korea and 329 Iran, Thailand and Malaysia have peaked in March. Indonesia and Saudi 330 Arabia would peak in April. Singapore and Japan recently implemented 331 lockdown and more data will be needed for the epidemic prediction. Given 332 the case-fatality rate at $2.3\%^6$, we estimated around 23,000 deaths in India 333 and Pakistan, and around 2,300 in Mexico and Brazil, and 6,900 in Russia. 334

This is the first study to compare country-specific temporal R_t . It is 335 natural to expect a declining trend of R_t to 1 owing to stochastic effects for epidemics governed by subexponential growth^{18, 30}, while a faster decline may 336 337 suggest a larger impact of intervention measures or behavior changes31. A 338 majority of countries displayed R_t below 5 in the first week of the epidemic 339 period. Several countries exhibited large R_t , ie. Italy or Spain, suggesting 340 a rapid increase of cases at the beginning or a large variation in the under-341 reporting rates in the early epidemic phase. For Wuhan, R_t declined from 342 the median 2.5 to 0.3 within a month, which is compatible with the R_0 estimation in a range of 2.2 to 3.6 in Wuhan^{2, 10, 12, 13, 16, 23, 31}, and below 1 after 343 344 interventions³². All countries displayed a declined trend towards 1 in the 345 epidemic period with varying deceleration rates, revealing the variation in 346 the impact of the intervention strategies. For further research on the in-347 tervention effectiveness, individual data, as well as a series of intervention 348 measures for each country, may be required to quantify the effects in detail. 349

Our study showed that by shortening the infectious period by two days, 350 we could effectively reduce the final epidemic size by up to 50%. What 351 strategies can effectively reduce the infectious period? Usually, it can be 352 done - similar to the other coronaviruses - by early detection and isolation of 353 symptomatic patients and tracing of close contacts. However, the presymp-354 tomatic transmission has been reported in many countries such as China, 355 the US, and Singapore³³⁻³⁶, etc. The existence of presymptomatic or asymp-356 tomatic transmission would present difficult challenges for disease control, 357 which underscores the importance of social distancing. For instance, at the 358 onset of the epidemic, the spread has been well controlled in Singapore, ac-359 counted for by a range of intervention measures, such as contact tracing and 360 quarantining, that were instituted from January 23-the onset of the first case 361 in Singapore³⁷. However, the recent increase in cases in Singapore, initially 362 starting from the imported cases followed by the outbreak in dormitories of 363 immigration workers, led to its circuit period from April 7 to May 4. Quar-364 antine measures for the infected regions or at the national scale, either a 365 complete lockdown as in China or partial lockdown such as in Europe, are 366 effective in flattening the curve³⁸. Besides the quarantine measures, South 367 Korea was also successful in suppressing the outbreak, attributed to the 368 rapid measures to perform large-scale diagnostic testing for the public for 369 case isolation³⁹. 370

During the early phase of the epidemic, we forecasted the epidemic size 371 as a function of the time-varying growth model, similar but more flexible to 372 the previous approaches to model sub-exponential growth dynamics^{18–21, 40} 373 without relying on any epidemiological parameter assumptions. The tradi-374 tional transmission epidemiological model is defined through a susceptible, 375 exposure, infectious, removed (SEIR) scheme, which requires epidemiological 376 parameters from detailed case studies^{2, 10, 31, 41}. Furthermore, given the varia-377 tion of the transmissibility, mostly due to the intervention strategies imple-378 mented and behavioral changes in the population, it is desirable to quantify 379 the dynamics of R_t over time^{20, 42-44}. Several studies attempted to forecast 380 the number of epidemics for COVID-19 in China using the constant growth 381 rate^{27, 45, 46}, which is not the case in our model of nonmonotonic behavior 382 of the growth rate. Our model, compared to previous studies, has greater 383 flexibility in a data-mining manner to fit and predict future trajectories. 384

In summary, we compared the epidemic trajectory, characterized dynamic R_t in 42 countries, and predicted that the new epidemic centers will continue to emerge in the next wave. Meanwhile, we highlighted the importance

of various effective interventions in flattening the epidemic curve, such as social distancing, to shorten the infectious period. By carefully characterizing the shape of the epidemic growth phase, we believe our study represents a significant step in modeling real-time transmission and providing accurate forecasts of epidemics.

Our study has several limitations. Firstly, the projection of the temporal 393 trend of an outbreak using the early-stage dataset could be dramatically 394 influenced by the changes in the intervention strategies later on. For example, 395 using data up to March 15, our previous analysis overestimated the epidemic 396 size in U.S as the social distance measures (i.e. quarantine) were implemented 397 starting from March 21. The performance of models used in this work will be 398 continuously improved with data coming in from an ongoing outbreak, thus 390 real-time estimates of key epidemiological parameters can be available before 400 the epidemic fully ends. Secondly, the number of infections estimated might 401 not be comparable across the countries; for example, the number of infections 402 in Germany is not comparable to the number of infections in Italy or China, 403 as the latter did not perform large-scale population-based testing and thus 404 the cases could be more severe. Lastly, the analyses are highly reliant on the 405 reporting criteria and quality of the data. The under-reporting of infection is 406 likely a common scenario in the majority of countries. For example, a recent 407 study showed that the reported number of confirmed positive cases was 50-408 85-fold lower than the actual number of infections in 3330 people in Santa 400 Clara County, US⁴⁷. A more realistic and comprehensive analysis could be 410 performed that includes accurate epidemic data and information. In current 411 imperfect situation, our model could still be used for more advanced analyses, 412 including estimations of the epidemic size, peak points and dynamic R_t . 413
