Abstract

Background The 2019 coronavirus disease (COVID-19) represents a significant public health threat globally. Here we describe efforts to compare epidemic growth, size and peaking time for countries in Asia, Europe, North America, South America and Australia in the early epidemic phase.

Methods Using the time series of cases reported from January 20, 2020 to February 13, 2020 and transportation data from December 1, 2019 to January 23, 2020 we have built a novel time-varying growth model to predict the epidemic trend in China. We extended our method, using cases reported from January 26, 2020 - or the date of the earliest case reported, to April 9, 2020 to predict future epidemic trend and size in 41 countries. We estimated the impact of control measures on the epidemic trend.

Results Our time-varying growth model yielded high concordance in the predicted epidemic size and trend with the observed figures in China. Among the other 41 countries, the peak time has been observed in 28 countries before or around April 9, 2020; the peak date and epidemic size were highly consistent with our estimates. We predicted the remaining countries would peak in April or May 2020, except India in July and Pakistan in August. The epidemic trajectory would reach the plateau in May or June for the majority of countries in the current wave. Countries that could emerge to be new epidemic centers are India, Pakistan, Brazil, Mexico, and Russia with a prediction of 10^5 cases for these countries. The effective reproduction

Preprint submitted to Journal

April 19, 2020

number R_t displayed a downward trend with time across countries, revealing the impact of the intervention remeasures i.e. social distancing. R_t remained the highest in the UK (median 2.62) and the US (median 2.19) in the fourth week after the epidemic onset.

Conclusions New epidemic centers are expected to continue to emerge across the whole world. Greater challenges such as those in the healthcare system would be faced by developing countries in hotspots. A domestic approach to curb the pandemic must align with joint international efforts to effectively control the spread of COVID-19. Our model promotes a reliable transmissibility characterization and epidemic forecasting using the incidence of cases in the early epidemic phase.

Keywords: Coronavirus, COVID-19, SARS-CoV-2, transmissibility, outbreaks, reproduction number R , generalized growth modeling

1. Introduction

In early December 2019, a novel severe acute respiratory syndrome coronavirus, SARS-COV-2, emerged into the human population in Wuhan, China¹⁻⁷. The first coronavirus disease 2019 (COVID-19) case outside China was reported on January 13, 2020 in Thailand. In just several weeks, the local transmission started rapidly in a broad array of countries in Asia, Europe, North America, South America and Australia, with the emergence of new epicenters of spread, such as the US, Italy, Spain, and France (<https://www.who.int>). The rapid spreading of SARS-COV-2 has led to a major global public health threat. The World Health Organization (WHO) declared the spread of COVID-19 a pandemic on March 11, 2020.

Early epidemic forecasts consisting of the likely trajectory of an unfolding outbreak can help guide the type and intensity of interventions⁸⁻¹⁰. The vast majority of these approaches considered early exponential growth dynamics, an assumption that could lead to substantial overestimation of epidemic size and peak timing. To enhance the ability to forecast epidemics, it is crucial to characterize the shape of epidemic growth and accurately assess early trends of sub-exponential growth phenomenon¹¹⁻¹³. Currently, the global case count continues to rise, but there is a limited understanding of the extent of the outbreak and epidemic growth profile, particularly for the new emerging epicenters.

22 In this study, we attempt to assess and compare the extent of the out-
 23 break across countries, draw preliminary conclusions about the impact of
 24 control measures, and characterize real-time effective reproduction number
 25 R_t . Our model, without making explicit assumptions about the epidemic
 26 growth profile, is a generalizable framework to estimate the early dynamic
 27 trends of COVID-19 from the incidences of cases. We estimated the epidemic
 28 trend and size in China using the cases reported from January 20, 2020 to
 29 February 13, 2020, and in other 41 countries using data from January 26,
 30 2020, - or the date of the earliest case reported, to April 9, 2020.

31 2. Methods

32 2.1. Sources of Data

33 We obtained the number of COVID-19 confirmed cases of time series
 34 data between January 20, 2020 to February 13, 2020 in China from the
 35 official websites of the National Health Commission of China and Provincial
 36 Health Committees (<http://www.nhc.gov.cn>). The data of cases for each
 37 of the 29 provinces (25 provinces plus 4 municipalities including Beijing,
 38 Shanghai, Chongqing and Tianjin) at 23 time points were included, as well
 39 as for Wuhan and major cities in Hubei. The start date of January 20 was
 40 chosen because the official diagnostic protocol released by WHO on January
 41 17 allows the new COVID-19 cases to be diagnosed accurately and rapidly.
 42 All cases were laboratory-confirmed with the detection of viral nucleic acid
 43 following the case definition by the National Health Commission of China.

44 Wuhan is connected to other cities in China via high-speed railway, high-
 45 way, and airplane flights. Population mobility statistics to estimate the ex-
 46 posed sizes in cities outside Wuhan were based on transport-related databases
 47 below: 1) Railway and airline travel data: the daily numbers of outbound
 48 high-speed trains from Wuhan with corresponding travelling hours were ob-
 49 tained from the high-speed rail network (<http://shike.gaotie.cn>) from Decem-
 50 ber 1, 2019 to January 23, 2020, and similarly daily numbers of outbound
 51 flight and hours for air transport were obtained from the Citytrip network
 52 (<https://www.ctrip.com>) from December 1, 2019 to January 23, 2020. We
 53 calculated daily travelling hours which equal to the product of the outbound
 54 trip counts and the travelling hours for rail and air transport respectively
 55 from Wuhan to each major city. For a given province, we summarized the
 56 total number of travelling hours across all cities in that province. 2) Highway
 57 mileage data: we collected highway mileage data from bus station networks at

58 <https://www.qichezhan.cn>. It contains the highway mileage from Wuhan to
59 16 cities in the Hubei Province. 3) Migration data: we obtained population
60 migration data from the Baidu Migration Map (<http://qianxi.baidu.com>)
61 which includes both the percentages and volumes of migration from Wuhan
62 to other cities and provinces from January 1 to 28, 2020. Total travelling
63 hours for rail and air flight, and migration scales are plotted by the province in
64 Supplementary Figure 1. Accumulated time on trains, on airplanes, highway
65 mileage and population migration scales were used to model the underlying
66 epidemic sizes in the provinces or cities outside Wuhan at the time 0 of this
67 study which is on January 20, 2020.

68 From Supplementary Figure 1, we observed that Guangdong has the
69 largest traveling hours through railway and airplane outbound from Wuhan
70 among the provinces. Also, the largest population has immigrated from
71 Wuhan to Henan. In Hubei province, Cities of Huanggang and Xiaogan are
72 the closest to Wuhan in terms of mileage and the scale of migration. These
73 simple observations are consistent with our result that Guangdong, Henan,
74 Huanggang and Xiaogan have the largest number of estimated primary in-
75 fected cases imported from Wuhan on January 20, 2020.

76 We obtained the number of COVID-19 confirmed cases in 41 countries
77 using data from January 23, 2020, or the date of the earliest case reported,
78 to April 9, 2020 from the official websites of WHO at <https://www.who.int>.
79 We included 41 countries with at least confirmed cases on April 9 2020 in five
80 continents: Asia, Europe, North America, South America, and Australia.

81 2.2. Modelling the transmissibility of COVID-19

82 We introduce the main notation here. All times are calendar times, mea-
83 sured in days since the start of the epidemic.

Y_{kt}	number of accumulated diagnosed case till day t ,
TR_k	daily traveling hours on trains from Wuhan,
FL_k	daily traveling hours on airplane from Wuhan,
RM_k	highway mileage from Wuhan,
MI_k	volumes of migration from Wuhan from January 1 to 28, 2020,
α_k	number of underlying primary infected cases,
W_{kt}	underline number of infected individuals who are infectious,
m	duration of infectious period (day),

where the subscript k represents country, province or city k , the subscript t represents day t . TR_k and FL_k are constructed based on the two reasons. One is that the longer people stay on the train or plane, the more likely he/she is to get infected. Another is that the infection happens in local area, hence the number of trains or planes has more information than the population taking trains or planes. In addition, in Hubei province, most people left Wuhan by cars, we use RM_k as one of measurement for the spatial distance between city k and Wuhan.

2.2.1. Modeling for 28 provinces

First, we build an index α_k to represent the baseline infected cases in province k on 20 January, 2020. Particularly, we will use TR_k , FL_k and MI_k to measure the relationship between province k and Wuhan. We suppose

$$\alpha_k = \beta_1 \times TR_k + \beta_2 \times FL_k + \beta_3 \times MI_k, \text{ for province } k, \quad (1)$$

where $\beta = (\beta_1, \beta_2, \beta_3)'$ are estimated by the observed Y_{kt} in provinces $k = 1, \dots, K$ and $t = 1, \dots, T$.

So far, we are not sure the key epidemiological parameters that affected spread and persistence. We hence make assumptions as least as possible. It is obvious that the average cases in province k diagnosed at day t is proportional to the scale of infectious cases on day $t-1$, $W_{k,t-1}$. We then assume a Poisson distribution for the new cases diagnosed in province k at day t with mean $\gamma_{kt}W_{k,t-1}$, that is

$$dY_{kt} = Y_{kt} - Y_{k,t-1} \sim \text{Poisson}(\gamma_{kt}W_{k,t-1}), \quad (2)$$

where ‘ $\sim$ ’ means ‘distributed as’.

Under the unified leadership of the central government, we suppose the trend of γ_{kt} over day t is the same for 28 provinces, that is, $\eta_{kt} = \eta_t$ is independent of k so that

$$\gamma_{kt} = \eta_t \times \gamma_{k,t-1}. \quad (3)$$

To avoid strong assumptions about the evolution of the epidemic, we allow η_t to be arbitray function of t . We determine the functional form of η_t by pointwise estimating η_t and checking the resulting pattern over t . Denote the resulting functional form for η_t by $\eta_t = \eta_t(a)$.

The new cases diagnosed at day t may be not reported fully. That is,

113 $E(dY_{kt}) = pdW_{kt}$ and $p < 1$. The estimation for p need more information
 114 except that we have. Fortunately, simple mathematical derivation shows
 115 that the value of p may influence the prediction of the absolute epidemic size
 116 but will not affect the trend of the epidemic, for example, the reproduction
 117 number, the duration and the peak time of the epidemic and relative epidemic
 118 size, in which we are interested. Hence, we suppose $p = 1$ in the paper. Since

$$W_{kt} = W_{k,t-1} + dW_{kt}, \quad dW_{kt} = E(dY_{kt}) = \gamma_{kt}W_{k,t-1}. \quad (4)$$

119 With the chain calculation, we have $dW_{kt} = \gamma_{kt} \prod_{j=0}^{t-1} (\gamma_{kj} + 1)W_{k0}$ and $W_{kt} =$
 120 $\prod_{j=0}^{t-1} (\gamma_{kj} + 1)W_{k0}$, where $W_{k0} = \alpha_k$ and $\gamma_{k0} = 0$. In practice, the infected
 121 patients will be isolated and removed from the infectious source. With the
 122 notation m of duration of infectious period, we hence have

$$W_{kt} = \prod_{j=0}^{t-1} (\gamma_{kj} + 1)\alpha_k - I(t > m) \prod_{j=0}^{t-(m+1)} (\gamma_{kj} + 1)\alpha_k. \quad (5)$$

123 Denote $\gamma_1 = (\gamma_{11}, \dots, \gamma_{K1})'$ and all of the parameters by $\delta = (\gamma'_1, a', \beta')'$.
 124 Taken (1), (2), (3) and (5) together, the loglikelihood function was

$$\begin{aligned} L(\delta) &= \sum_{k=1}^K \sum_{t=1}^T \{dY_{kt} \log(\lambda_{kt}) - \lambda_{kt}\} + C \\ &= \sum_{k=1}^K \sum_{t=1}^T (dY_{kt} \log[\gamma_{kt} X_k^T \beta \{\prod_{i=1}^{t-1} (1 + \gamma_{ki}) - I(t > m) \prod_{i=1}^{t-m} (1 + \gamma_{ki})\}]) \\ &\quad - \gamma_{kt} X_k^T \beta \{\prod_{i=1}^{t-1} (1 + \gamma_{ki}) - I(t > m) \prod_{i=1}^{t-m} (1 + \gamma_{ki})\}) + C, \end{aligned} \quad (6)$$

125 where C is a constant independent of δ , m is determined by minimizing
 126 the prediction error. The confidence intervals were obtained based on 200
 127 bootstrap resampling^{14, 15}.

128 2.2.2. Modeling for Hubei, Wuhan and the other countries

129 The modeling and the loglikelihood function for Hubei are similar with
 130 those for 28 provinces except that FL_k is replaced by RM_k and provinces are
 131 replaced by cities, because there are not flights between the cities in Hubei
 132 and Wuhan, and the most people leave Wuhan by cars or buses. Specifically,

$$\alpha_k = \beta_1 \times TR_k + \beta_2 \times RM_k + \beta_3 \times MI_k, \quad \text{for city } k \text{ in Hubei.} \quad (7)$$

133 The modeling and the likelihood function for Wuhan and countries, in-
134 cluding Singapore, South Korea, Japan, Italy, German, Spain, France and
135 Iran, are similar with those for 28 provinces except that α_k is directly esti-
136 mated by the diagnosed cases in Wuhan and other 41 countries respectively.

137 2.2.3. The calculation of the time-dependent reproduction number R_t

138 The equation $dW_{kt} = \gamma_{kt}W_{k,t-1}$ implies that, when $W_{k,t-1} = 1$, we have
139 $\gamma_{kt} = dW_{kt}$. Hence γ_{kt} is the average number of new infections created by an
140 infectious individual in one day, then $\phi_t = \sum_{k=1}^K \gamma_{kt}/K$ is the corresponding
141 average number across provinces or cities. Since one infectious individual
142 can make infection for m days, an infectious individual then can lead to
143 $R_t = m\phi_t$ new infections, which indeed is the time-dependent reproduction
144 number^{16, 17}.

145 2.2.4. Predication of potential peak time and turning point in COVID-19 146 outbreak

147 With the estimated parameters by maximizing the loglikelihood (6), we
148 can estimate and predict the average new cases $dW_{kt} = \gamma_{kt} \prod_{j=0}^{t-1} (\gamma_{kj} + 1)\alpha_k$,
149 then the cumulative cases $\tilde{W}_{kt} = \prod_{j=0}^t (\gamma_{kj} + 1)\alpha_k$. Based on the new cases
150 and cumulative cases, we can predict the peak time and the turning point in
151 the COVID-19 outbreak. In the paper, we defined the peak time to be the
152 day at which the incidence cases began to decline, and the turning point to
153 be the day when the number of the cumulative cases reached a plateau, which
154 satisfying $|\partial f(v)/\partial v| \leq c_0$, where $f(v) = \frac{\partial \tilde{W}_{kt}/\partial t|_{t=v}}{\partial \tilde{W}_{kt}/\partial t|_{t=v-1}}$ and c_0 is a prespecified
155 small number. We take $c_0 = 2e - 03$ through the analysis.

156 3. Results

157 3.1. Fitting a generalized growth model using a time-series data

158 We fit the time-varying generalized growth model using the early stage
159 outbreak series data for Wuhan, Hubei province, China, and other 41 coun-
160 tries with at least 2,000 confirmed cases on the date of April 9 2020. The
161 optimal fitted model for each country or region was chosen based on the
162 prediction error of the lowest values (Supplementary Figures 2 to 4). The
163 corresponding empirical distributions of the parameters are shown in Table
164 1. The parameter m , the estimated mean infectious duration, ranged from 4
165 to 13 days, with the highest value of 13 for the epidemic in Italy. The short

duration of 4 days was estimated for South Korea. The value of m reflects the duration of infectious period, which in practice could be intervened by control measures such as early diagnosis and isolation. Another parameter $\eta(t)$ quantifies how rapidly the growth rate $\gamma(t)$ at time t changed; the functional form of $\eta(t)$ was estimated by pointwise estimation using data till t for each model respectively. The growth rates declined most rapidly in China and Thailand (median η : 0.86 to 0.89), and most slowly in India, Mexico, Singapore and Sweden (median η : 0.98 to 0.99).

3.2. Predictive performance of model fitting

Using the calibrated model based on m and the form of $\eta(t)$, we estimated the real-time growth rates based on the number of confirmed cases at $t = 1, \dots, T$ by maximizing the likelihood function displayed in the Method section. The underlying growth process was lower than the constant exponential growth rate as medium $\eta(t)$ was consistently estimated at less than 1 (Supplementary figure 3), similar to findings of sub-exponential growth dynamics for epidemics of influenza, Ebola etc with the deceleration growth factor below 1^{18, 19}.

For China, we used case incidence data from January 20 to February 13 as the epidemic reporting period to fit the model for trajectory predictions. The observed values fall within 95% CI of the prediction band in general, suggesting a good model fitting (Figure 1 and Supplementary Figures 8-9). We predicted that the epidemics would fade out around February 19 to 24 across the 28 provinces, about 4 weeks after the intervention starting from January 20; this is in concordance with the actual timing in which no more new cases were observed at the end of February (<http://www.nhc.gov.cn>). For 28 provinces in China, the estimated size was at 8553 to 9460 and 11,000 to 12,600 for Hubei province; both 95% CI estimates cover the observed figures (Table 2). For Wuhan, due to the changes in the diagnosis criteria, the predicted number of cases was not comparable after February 13. We estimated the epidemic would fade out around the end of February, which is close to the final date in which no more new cases were observed in Wuhan.

Within each province, the observed final epidemic size was within the 95% CIs of prediction except 5 provinces, yet the prediction was still within 10% +/- flanking the upper or lower bound (Supplementary Table 1). Given the intervention measures are similar across provinces in China besides Hubei, it is not surprising that we observed the trend that the provinces with a higher estimated risk of imported cases alpha from Wuhan had an increased

epidemic size. However, there were some exceptions. For example, Beijing ($\alpha = 28$; 95%CI : 7 – 49) and Shanghai ($\alpha = 16$; 4 – 28) were in the high-risk group but the final infection numbers were 286 and 261. On the contrary, Heilongjiang was in the low-risk group ($\alpha = 4$: 1 – 6) whereas the final infections were at 252. This implies the stronger intervention locally or compliance in densely populated municipalities (Beijing or Shanghai), than that in Heilongjiang, the north-east region far away from Wuhan. Overall our time-varying growth model provides a good fitting using time-series confirmed cases for the epidemic of COVID-19 in China.

3.3. Projection of the epidemic and final size in 41 countries

We projected the future growth trajectory underlying the outbreak using the daily confirmed case data from January 23, 2020 - or the date of the earliest case reported - to April 9, 2020 in 42 countries across Asia, Europe, North America, South America and Australia. Our prediction is based on the estimated parameters assuming the sustainability of intervention measures. The time-varying growth model fitting to the time-series data performed well as shown by the observed cases generally falling in the 95% CI of the prediction bound in each plot (Figure 1 and Supplementary Figures 8-12), except for South Korea in the very early phase. The predicted cases were higher than the observed number of infections from February 8 to 25, likely due to a proportion of infections being greatly understated - the hiding cases from the religious group.

We predicted the epidemic size and duration of the outbreak with the assumption of current model fitting parameters (Table 2). In Asia, the epidemic will continue until May in Philippine, Malaysia and Iran, and July in Indonesia. Strikingly, the epidemic would have the longest outbreak spread until February or March 2021 in Indian and Pakistan, with the final infections at more than a million. For Japan and Singapore, we were not able to do predictions on the epidemic sizes and duration because the estimated time-varying growth rates kept on increasing at the end of the study period – which is concordant to the big daily jump in cases observed in these two countries recently; thus incidence case data in a longer period are required for valid predictions using our model. In Europe, the epidemic will not fade out until May or June for the majority of countries. However the epidemic may last until August (Russia and Sweden). In North America, the epidemic will continue until May (Canada, Dominican Republic), June (US) and October (Mexico), and the infection are estimated to be around 1 million in the US,

240 and 10^5 in Mexico. In South America, the epidemic will continue until May
241 (Chile) and June (Brazil, Colombia and Panama). Among them, Brazil has
242 the largest estimated infections with more than 10^5 .

243 3.4. *Estimation of peak time*

244 We estimated the peak time, the day at which the incidence cases began
245 to decline based on the estimated daily cases dW_{kt} (see [Methods](#)). Among 41
246 countries, the peak time has been observed in 28 countries before or around
247 April 9, 2020 (Table 3 & Supplementary Figures 13-15). The estimations
248 in the above countries are concordant to the observed period during which
249 incidence cases declined. For other countries, under the current parameters
250 with continuity of intervention measures, we estimated the epidemic would
251 peak in April or May 2020 for the majority of countries, except for India
252 (July) and Pakistan (August). The predicted numbers of accumulated cases
253 at the peak point were also consistent with the observed figures. Based on
254 the predicted number of infections, we estimated the maximum number of
255 ventilators for the peak requirement. For example, at least 500,000 venti-
256 lators need to be prepared for the epidemic peak in India, $\sim 100,000$ for
257 Pakistan. Considering the death or recovery rate, the number is regarded as
258 the upper bound in practice.

259 3.5. *Impact of the reduction of the infectious period*

260 Shortening the time from the infection onset (symptomatic or asymp-
261 tomatic) to isolation, termed as ‘infectious period’ in this paper, is vital as
262 it will reduce transmission. The control strategies could rely on social dis-
263 tancing, earlier isolation of cases and population-based testing to identify
264 the presymptomatic or asymptomatic cases. Here we evaluated the impact
265 of shortening the infectious period on the epidemics, showings the epidemic
266 curve for each country, assumed to be 1 or 2 days shorter in the duration
267 of infectivity infectious period (Supplementary Figures 13-15). A reduction
268 of the infectious period by 1 or 2 days would have a negligible effect on the
269 peak time, as the estimation was essentially the same. The reduction of the
270 infectious period by 1 or 2 days would lead to a significantly flatted epidemic
271 curve across all the countries. For example, the 2-days decrease in the in-
272 fectious period would result in a significant reduction of the final epidemic
273 size in India (31.1%), Pakistan (39.3%), Russia (22.6%), Brazil (26.8%), and
274 Mexico(18.0%).

275 3.6. Estimation of real-time effective reproduction number R_t

276 We quantified the real-time reproduction number R_t (see [Method sec-](#)
277 [tion](#))^{17, 20, 21}, based on the estimation parameters of growth rates γ and the
278 infectious period m . The R_t exhibited a declining trend with time and vari-
279 ability in the estimates across countries (Table 4). The uncertainty of R_t
280 was largest in the first week and gradually became smaller with time (Table
281 4). In the first week, 28 countries displayed R_t below 5 while 14 exhibited
282 large R_t above 5. Italy and Spain displayed the highest R_t at 12.36, and 9.26
283 respectively. R_t estimations become closer ranging from 0.95 (Singapore)
284 to 5.54 (Spain) in the second week. During the first month of the epidemic
285 period, all countries displayed a declined trend towards 1 in the epidemic pe-
286 riod with varying deceleration rates, revealing the impacts of the intervention
287 strategies. In the fourth week, 14 countries exhibited R_t below 1, the highest
288 in UK (2.62) and the US (2.19). For Singapore and Japan, although both
289 displayed the declining trend in the first month, there is an inclining trend
290 starting from April, implying the intervention could not be effective in the
291 late stage (Supplementary Figure 16). R_t displayed the fastest deceleration
292 in China with the most pronounced changes during the third to fourth weeks;
293 this may reveal the significant impact of intervention measures implemented
294 since January 20, 2020 in the first week.

Table 1: Summary of fitting parameters for the selected model in 10 countries in 2020.

	Epidemic study period	m	Medium η_t (95%)	form of η_t
Asia				
China	01/20– 02/13	6	0.89(0.87, 0.91)	$a_0 + a_1(t - t_1) - + a_2(t - t_2) -$
Hubei Province, China	01/20– 02/13	9	0.86(0.84, 0.88)	$a_0 + a_1(t - t_1) - + a_2(t - t_2) -$
Wuhan, China	01/20– 02/13	6	0.88(0.86, 0.90)	$a_0 + a_1(t - t_1) - + a_2(t - t_2) -$
India	03/04–04/09	9	0.99(0.98, 1.00)	$a_0 + a_1(t - t_1) -$
Indonesia	03/08–04/09	10	0.97(0.96, 0.98)	$a_0 + a_1(t - t_1) -$
Iran	03/19–04/09	8	0.96(0.96, 0.98)	$a_0 + a_1(t - t_1) -$
Japan	02/14–04/09	8	0.97(0.96, 0.98)	$a_0 + a_1(t - t_1) -$
South Korea	01/24– 04/09	4	0.93(0.92, 0.94)	$a_0 + a_1(t - t_1)I(t_1 \leq t \leq t_2) + a_1(t_2 - t_1)I(t > t_2)$
Malaysia	02/27–04/09	11	0.94(0.93, 0.95)	$a_0 + a_1(t - t_1) - + a_2(t - t_2) -$
Pakistan	03/09–04/09	6	0.92(0.89, 0.95)	$a_0 + a_1(t - t_1) - + a_2(t - t_2) -$

Australia						
Australia	0.266(0.233, 0.298)		2020/04/16	-	4932 ~ 6969	-

The ending date is the day when the number of the cumulative cases reach a plateau (see [Methods](#)). For Japan and Singapore, the predicted trend does not reach a plateau because of increasing growth rate at last time points (Supplementary Figure 3(h) & 4(h))

Figure 1: The estimated (red-solid) and observed (black-dotted) cumulative number of infectious over time t , as well as 95% CI (red-dashed) of the estimators. In addition, the green dots in the plot for Beijing and Guangdong in China refer to the number of reported cases which were not included for the model fitting.

Table 3: The predicted or observed peak date and the corresponding cumulated size among the different countries

		Peak date		# Maximum cases at the peak		# Ventilator needed for the peak
		Prediction	Observation	Prediction	Observation

* Peak date has been observed. Due to the fluctuation of the daily reported cases, the observed peak interval was listed instead of the exact peak date.

The number of maximum cases at the peak is the accumulated number of cases at the peak period.

The number of ventilator for the peak requirement is calculated based on the predicted infection. We assume 5 – 10% of the infected patients need the ventilator²².

Figure 2: The proportion of epidemic size when the duration of infectious period m is reduced by 1 and 2. The reduction of infectious duration refers to shorten the time from the infection onset (symptomatic or asymptomatic) to isolation by intervention measures.

295 4. Discussions

296 Here we predicted that the COVID-19 pandemic will persistently spread
 297 over many countries and will last on average 5 to 6 months since January 2020
 298 for the current wave. We estimated, given no further intervention measures,
 299 that India would emerge to be a new epidemic center, as well as Pakistan,
 300 Brazil, Russia and Mexico. Effective intervention measures by reducing the
 301 infectious period would result in an 50% reduction in the final epidemic sizes.
 302 R_t had a declining trend in almost all countries, revealing the impact of the
 303 intervention measures i.e. social distancing.

304 Our real-time estimation framework can yield a reliable prediction of
 305 the final epidemic size using the data from the early phase of the epidemic.
 306 We evaluated the performance of our model using incident case data from
 307 January 20 to February 13, 2020 in China. We predicted the epidemic would
 308 fade out on February 19 to 24 across 28 provinces in China with a one-
 309 week lag in Wuhan; the epidemic size was estimated at 8,500 to 9,500, and
 310 11,000 to 12,600 in 28 provinces and Hubei respectively. The outbreak size
 311 and epidemic duration estimated are found to be highly consistent with the

observed figures (<https://www.who.int>). The prediction of the final epidemic size based on the model that assumes early exponential growth could tend to overestimate the epidemic size, which has been shown in the previous studies^{10, 23-28}.

We estimated that the most affected countries in the next wave of the pandemic will be India, Pakistan, Brazil, Mexico as well as Russia. All these countries are currently undergoing regional or national lockdown except Mexico. Given that thousands of ventilators are needed for the peak around May to July, it is immediately important for these countries to prepare the ICU beds. In Europe, most countries have peaked in the curve, and the final outbreak size was estimated to exceed 10^5 in Italy, France, UK, Germany and Spain. For the United States, the estimated final epidemic size will surpass 1 million, peaking around July 2020. A recent report calculated that 81% of British and the United States populations would be infected, with approximately a half and 2.2 million deaths respectively²⁹. The high value is based on the assumption of R_0 at 2.4, while our results demonstrate that real-time R_t decelerated under interventions. Thus, their estimates are likely to be the higher bound of the true value. In Asia, besides China, South Korea and Iran, Thailand and Malaysia have peaked in March. Indonesia and Saudi Arabia would peak in April. Singapore and Japan recently implemented lockdown and more data will be needed for the epidemic prediction. Given the case-fatality rate at 2.3%⁶, we estimated around 23,000 deaths in India and Pakistan, and around 2,300 in Mexico and Brazil, and 6,900 in Russia.

This is the first study to compare country-specific temporal R_t . It is natural to expect a declining trend of R_t to 1 owing to stochastic effects for epidemics governed by subexponential growth^{18, 30}, while a faster decline may suggest a larger impact of intervention measures or behavior changes³¹. A majority of countries displayed R_t below 5 in the first week of the epidemic period. Several countries exhibited large R_t , ie. Italy or Spain, suggesting a rapid increase of cases at the beginning or a large variation in the under-reporting rates in the early epidemic phase. For Wuhan, R_t declined from the median 2.5 to 0.3 within a month, which is compatible with the R_0 estimation in a range of 2.2 to 3.6 in Wuhan^{2, 10, 12, 13, 16, 23, 31}, and below 1 after interventions³². All countries displayed a declined trend towards 1 in the epidemic period with varying deceleration rates, revealing the variation in the impact of the intervention strategies. For further research on the intervention effectiveness, individual data, as well as a series of intervention measures for each country, may be required to quantify the effects in detail.

Our study showed that by shortening the infectious period by two days, we could effectively reduce the final epidemic size by up to 50%. What strategies can effectively reduce the infectious period? Usually, it can be done - similar to the other coronaviruses - by early detection and isolation of symptomatic patients and tracing of close contacts. However, the presymptomatic transmission has been reported in many countries such as China, the US, and Singapore³³⁻³⁶, etc. The existence of presymptomatic or asymptomatic transmission would present difficult challenges for disease control, which underscores the importance of social distancing. For instance, at the onset of the epidemic, the spread has been well controlled in Singapore, accounted for by a range of intervention measures, such as contact tracing and quarantining, that were instituted from January 23-the onset of the first case in Singapore³⁷. However, the recent increase in cases in Singapore, initially starting from the imported cases followed by the outbreak in dormitories of immigration workers, led to its circuit period from April 7 to May 4. Quarantine measures for the infected regions or at the national scale, either a complete lockdown as in China or partial lockdown such as in Europe, are effective in flattening the curve³⁸. Besides the quarantine measures, South Korea was also successful in suppressing the outbreak, attributed to the rapid measures to perform large-scale diagnostic testing for the public for case isolation³⁹.

During the early phase of the epidemic, we forecasted the epidemic size as a function of the time-varying growth model, similar but more flexible to the previous approaches to model sub-exponential growth dynamics^{18-21, 40}, without relying on any epidemiological parameter assumptions. The traditional transmission epidemiological model is defined through a susceptible, exposure, infectious, removed (SEIR) scheme, which requires epidemiological parameters from detailed case studies^{2, 10, 31, 41}. Furthermore, given the variation of the transmissibility, mostly due to the intervention strategies implemented and behavioral changes in the population, it is desirable to quantify the dynamics of R_t over time^{20, 42-44}. Several studies attempted to forecast the number of epidemics for COVID-19 in China using the constant growth rate^{27, 45, 46}, which is not the case in our model of nonmonotonic behavior of the growth rate. Our model, compared to previous studies, has greater flexibility in a data-mining manner to fit and predict future trajectories.

In summary, we compared the epidemic trajectory, characterized dynamic R_t in 42 countries, and predicted that the new epidemic centers will continue to emerge in the next wave. Meanwhile, we highlighted the importance

of various effective interventions in flattening the epidemic curve, such as social distancing, to shorten the infectious period. By carefully characterizing the shape of the epidemic growth phase, we believe our study represents a significant step in modeling real-time transmission and providing accurate forecasts of epidemics.

Our study has several limitations. Firstly, the projection of the temporal trend of an outbreak using the early-stage dataset could be dramatically influenced by the changes in the intervention strategies later on. For example, using data up to March 15, our previous analysis overestimated the epidemic size in U.S as the social distance measures (i.e. quarantine) were implemented starting from March 21. The performance of models used in this work will be continuously improved with data coming in from an ongoing outbreak, thus real-time estimates of key epidemiological parameters can be available before the epidemic fully ends. Secondly, the number of infections estimated might not be comparable across the countries; for example, the number of infections in Germany is not comparable to the number of infections in Italy or China, as the latter did not perform large-scale population-based testing and thus the cases could be more severe. Lastly, the analyses are highly reliant on the reporting criteria and quality of the data. The under-reporting of infection is likely a common scenario in the majority of countries. For example, a recent study showed that the reported number of confirmed positive cases was 50-85-fold lower than the actual number of infections in 3330 people in Santa Clara County, US⁴⁷. A more realistic and comprehensive analysis could be performed that includes accurate epidemic data and information. In current imperfect situation, our model could still be used for more advanced analyses, including estimations of the epidemic size, peak points and dynamic R_t .
