Abstract

Background COVID-19 is a virus which has lead to a global pandemic. Worldwide, more than 130 countries have imposed severe restrictions, which form part of a set of non-pharmaceutical interventions (NPI)s. We aimed to quantify the country-specific effects of these NPIs and compare them using the Oxford COVID-19 Government Response Tracker (OxCGRT) stringency index, p , as a measure of NPI stringency.

Methods We developed a dual latent/observable Susceptible Infected Recovered Deaths (SIRD) model and applied it on each of 22 countries and 25 states in the US using publicly available data. The observable model parameters were extracted using kernel functions. The regression of the transmission rate, β , as a function of p in each locale was modeled through the interven-

tion leverage, α_s , an initial transmission rate, β_0 and a typical adjustment time, b_r^{-1} .

Results The world average for the intervention leverage, $\alpha_s = 0.01$ (95% CI 0.0102 - 0.0112) had an ensemble standard deviation of 0.0017 (95% C.I. 0.0014 - 0.0021), strongly indicating a universal behavior.

Discussion Our study indicates that removing NPIs too swiftly will result in the resurgence of the spread within one to two months, in alignment with the current WHO recommendations. Moreover, we have quantified and are able to predict the effect of various combinations of NPIs. There is a minimum NPI level, below which leads to resurgence of the outbreak (in the absence of pharmaceutical and clinical advances). For the epidemic to remain sub-critical, the rate with which the intervention leverage α_s increases should outpace that of the relaxation of NPIs.

Keywords: COVID-19, Model, Control

1. Introduction

A novel corona virus, named COVID-19, was detected in the Hubei province of China in late December 2019 and rapidly spread resulting in a confirmed global pandemic by 11 March 2020¹. As at 26 April 2020, the total number of infections has exceeded 3.1 million confirmed cases with more than 210 thousand deaths worldwide attributable to the effects of the virus². A large, worldwide modeling effort is currently underway to improve health policy decision making with regards to the COVID-19 pandemic³⁻⁷. Many research groups and national response teams have looked into country specific intervention strategies^{4,6-9}.

Recently, the total level of NPI stringency has been classified by the Oxford COVID-19 Government Response Tracker (OxCGRT) team and a nominal index measure has been defined for use by the wider international community. We address the use of this index measure to establish the degree and characteristics of control of the transmission rate of the virus within a representative sample of countries in the World and states in the United States of America.

19 2. Research in Context

20 2.1. Evidence before this study

21 Multiple teams have produced epidemic models which allow for the pre-
 22 diction of response to NPIs within their given locale. The typical complexity
 23 and bespoke nature of these models has meant that transferring insights from
 24 one country to another has been challenging. Comparing sufficient statistics
 25 (where they have been defined) amongst multiple other countries has not
 26 been done before.

27 2.2. Added value of this study

28 By comparing a wide variety of locales; we have shown a universality of
 29 *form* in response to changes in NPIs. Our modeling paradigm is succinct
 30 and requires only a few observable parameters to be measured in addition
 31 to what is presently done for successful control. These parameters allow for
 32 predicting not only *how much* effect a given NPI level has, but also *how long*
 33 we need to wait before we observe the effects.

34 2.3. Implications of the available evidence

35 The insight our research offers is a worldwide survey of the dynamics and
 36 characteristics various countries possess with regards to the control of the
 37 pandemic, through non-pharmaceutical interventions (NPI)s. Policy makers
 38 may now gradually control their local epidemic within their contextual situ-
 39 ation without having to rely on the parameters derived from other country-
 40 specific intervention studies. This quantification allows policy makers to
 41 define safe limits of control.

42 3. Method

43 For a fair comparison of the effect of interventions, carefully curated,
 44 comprehensive and frequently updated data is a requirement. Data was,
 45 therefore, sourced from the Johns Hopkins COVID-19 data repository be-
 46 cause it fulfilled both the due diligence and frequency of updating needed for
 47 this research.¹⁰

48 Using this existing data up to and including 26 April 2020, multiple SIRD
 49 with latent dynamics and error propagation models (see Appendix B for full
 50 details) were employed. The chosen modeling method is simpler than others
 51 used in this pandemic.⁷ This is a feature since it is 'mind-sized' and has a

number of sufficient statistics needed to understand the response to control. An initial cohort of 23 countries and 25 states within the United States of America were chosen to be as representative and diverse as possible. Levels of control were measured by the Oxford COVID-19 Government Response Tracker (OxCGRT) stringency index.¹¹ This index, denoted p in our work, takes values from 0 to 100 and is indicative of the severity and number of discrete measures that have been taken to try to curb the spread of COVID-19.¹¹ At the time of writing; America did not have a stringency index published. Incorporating their reported NPIs into the OxCGRT framework described fully in Appendix A. Daily parameter estimates of the models were extracted from the data using a least-squares framework and candidate kernel functions were regressed on the daily parameter estimates. These kernel functions represent the time domain response of a model parameter to a given level of control and are based on a dynamic hypotheses that additive effects of random variables contribute to the observed effects of intervention.¹² This sort of exponential behaviour will cease to be representative if there is a systematic breakdown in roll-out of the interventions (so called 'fat tails').¹³ If such a systematic breakdown were to happen, our proposed kernel functions would cease to be valid.

3.1. Model

The characteristics of the present pandemic are atypical in that infected individuals may be asymptomatic and infectious.¹⁴ To this end, we developed a dual observable/latent SIRD model to capture the essential features of the present COVID-19 outbreak and allow for clear interpretation with regards to control and decision making. This model is depicted in Figure 1 and has several key parameters which completely characterise the behaviour. The latent dynamics are essential to capture the following clinical properties of COVID-19:

1. Asymptomatic cases are infectious^{15,16}.
2. It is possible for deaths to be overstated since positive tests are not a requirement in some locales for establishing the basic underlying cause of death in this pandemic; reasonable clinical judgement is¹⁷. In addition, overstatements in clinical cases may be due to the highly infectious

88 nature of the virus; patients with severe comorbidities may not neces-
89 sarily die with the virus as the basic underlying cause even though it
90 is likely to be present in the patient if they are admitted to a facility
91 with many active COVID-19 cases.

92 3. There are early reports that the latent prevalence (using a seropreva-
93 lence study) may be as high as 14% of one of the most densely populated
94 cities in the World¹⁸.

95 4. There have been serious calls for protection of front-line health care
96 workers as a result of early experiences with the epidemic^{19,20}. The
97 nosocomial infections within hospital care providers as a group may be
98 non-negligible, though for the large scale model we are considering, this
99 group has not been partitioned separately.

100 The observable (directly measurable) dynamics capture the standard features
101 of susceptible portions of the population becoming infected and then either
102 recovering with perpetual immunity or dying.

103 There is evidence that relapse is possible, where recovered patients would
104 become susceptible again²¹. This model variation has not been explicitly
105 considered because do not know the significance of this yet; it is possible that
106 these are people who were not fully cured²¹, they may have been reinfected
107 with a different strain¹⁶, the reverse transcription polymerase chain reaction
108 (RT-PCR) test can give a positive result due to extracellular RNA, shedding
109 of non-viable virions etc.

110 Of note is that the implicit assumption with this approach is that there is
111 a single viral strain which is being modelled. If there are multiple strains,
112 each of which is observable and differentiable through specialised testing then
113 refinements on the labelling and parameters are possible.

114

115 3.2. *Observable Dynamics*

116 Under the stated clinical conditions the transmissions between known in-
117 fected patients, I , and susceptible individuals (in the broadest sense possible)
118 should be rare. The typical disease progression time frame^{14,22} implies that
119 latent infections leading to deaths should be rare, it is presumed that patients
120 with severe symptoms are brought in for treatment. Under these conditions
121 the latent dynamics in the model simplify with $\delta_L \approx 0$ and $\beta \approx 0$ and this
122 model simplification is used throughout.

123 What is observed then, in terms of increase in measured infections I , is

Figure 1: SIRD model with Unobserved Latent Dynamics.

124 achieved strictly through ϕI_L . These are the detected infections and depen-
 125 dent on the detection rate, ϕ .

126

127 3.3. Daily observed infection rate, ϕ

128 An important component for estimating ϕ is the number of positive in-
 129 dividuals who do not know their status and are asymptomatic. Random
 130 testing has proven useful in this regard in Iceland¹⁶ and New York¹⁸.
 131 Reliable estimates of asymptomatic cases due to either extensive randomised
 132 testing or exhaustive testing in closed populations are presented in Table 1.
 133 Unfortunately, the number of asymptomatic cases are approximately 50%
 134 of all positive COVID-19 patients. The fraction of asymptomatic cases in
 135 enclosed populations, the number of patients with antibodies present (due to
 136 randomised population seroprevalence studies) and patients with symptoms
 137 who are sub-clinical and do not warrant admission and formal testing will
 138 also all influence the rate measured by ϕ .

139 3.4. Kernel functions

140 The roll-out of any country-wide control measure is subject to random
 141 variations in timing and levels of civil compliance dependent on the execu-

Table 1: Results from various studies regarding the number of asymptomatic cases amongst those testing positive for COVID-19.

tion plan and the populace's disposition. This was modeled with the kernel function, conditioned on the control measure p :

$$\beta_p(t) = (1 + b_0 e^{-b_r \Delta t}) \beta_f(p), \quad (1)$$

where $\beta_f(p)$ is the asymptotic value of the observed daily transmission rate, b_r is the typical adjustment rate and b_0 is used to model the initial transmission rate before the control p is applied. A characteristic plot is depicted in Figure 2.

As a starting point, it is hypothesised that the typical adjustment rate b_r is characteristic of a nation and that $\beta_f(p)$ is dependent on the stringency of control p through:

$$\beta_f(p) = \beta_0(1 - \alpha_s p), \quad (2)$$

where α_s is the intervention leverage. In the absence of data on the population dynamics during withdrawal of some NPI's, our model is conservative and uses the same typical adjustment rate for the withdrawal of NPI's as for the addition of NPIs.

The kernel function for $\gamma(t)$ is:

$$\gamma_p(t) = \gamma_0, \quad (3)$$

regardless of control. The clinical and physical justification for this model is that the inherent properties of the recovery process do not change with non-pharmaceutical control, assuming the hospital system has not been overwhelmed yet.

Figure 2: The transmission rate kernel function depicting the typical adjustment rate, b_r and final transmission rate β_f . The control index p affects the total reduction in transmission.

161 The kernel function for $\delta(t)$ is:

$$\delta_p(t) = d_0 t^{d_1} e^{-d_r \Delta t}, \quad (4)$$

162 which is the result that would be theoretically expected from a cascade of
 163 first order processes²⁷. The temporary increase in this parameter is due to
 164 the reduced number of severe infections which will artificially raise it since
 165 $\delta \propto I^{-1}$, see (B.7). This function captures the transients inherent in the
 166 daily death count as a result of intervention only.

167 3.5. Control

168 The capacity of countries to properly address the risk that COVID-19
 169 poses is varied; with less than half being fully positioned to prevent, detect,
 170 and respond appropriately²⁸. The World Health Organisation identifies the
 171 need to reduce human-to-human transmission of the virus using numerous
 172 public health measures.²

173 The effect of these various control policies on our latent model are depicted
 174 in Figure 3. This Figure clearly demonstrates the value of the proposed
 175 methodology; one may holistically view the epidemic and various policy ac-
 176 tions in a single framework and be able to anticipate the consequences.

177 A method to measure the overall level of control is described next.

Figure 3: The Effects of Various Interventions on the Model

3.6. NPIs and the OxCGRT Stringency Index

The OxCGRT has developed a valuable database for comparing countries response strategies.²⁹ The database contains the following levels of control (coded using ordinal numbers) and timing for 139 countries:

1. S1 - School closure
2. S2 - Workplace closure
3. S3 - Cancel public events
4. S4 - Close public transport
5. S5 - Public information campaign
6. S6 - Domestic travel bans
7. S7 - International travel bans

Also included in this data set is a Stringency Index, p in our notation, which provides a single number that captures the overall level of intervention implied by combinations of the ordinal numbers S1-S7. The Oxford stringency index is calculated using a weighted average of the above seven non-pharmaceutical interventions³⁰.

As an example of the use of this index, the overall intervention level is depicted in Figure 4, plotted against the number of days since the first reported COVID-19 case.

Figure 4: Timing and Severity of NPIs in our set of representative countries and US

198 4. Results

199 The results, using the foregoing methodology are shown in Table 2 for
 200 the selected countries in this study and in Table 3 for selected States of the
 201 US. Results are expressed in terms of γ_0 , d_0 , β_0 , b_r^{-1} , p_{max} and α_s in Table 2.
 202 Table 3 does not display γ_0 , as the data for the number of recoveries has
 203 not been reported in the US since late March¹⁰. The first salient feature of
 204 Tables 2 and 3 is that the evolution of the pandemic in different countries
 205 share strong similarities. Some variations are observed in the parameters γ_0 ,
 206 d_0 , β_0 , where b_r^{-1} is subjected to features of the data most likely to specifics
 207 in the reporting. Of note though is the consistency of α_s .

208 4.1. Ensemble variation of intervention leverage, α_s

209 With a formal treatment, the following ensemble characteristics are ob-
 210 served with regards to the intervention leverage across all locales: the en-
 211 semble average intervention leverage is given by $\alpha_s = 0.01$ (95% CI 0.0102
 212 - 0.0112) and the ensemble standard deviation is given by 0.0017 (95% C.I.
 213 0.0014 - 0.0021). These results depend on the respective marginalisation over
 214 a Gaussian noise process, a flat prior probability for the mean and a Jeffrey's
 215 prior for the variance.¹² Note that there were two outliers that were removed
 216 from this calculation, Sweden and North Dakota and they are left for discus-
 217 sion.

218 Using the values from Tables 2 and 3, the expected control surfaces which

Figure 5: Comparison of ensemble average NPI stringency index, p against the ensemble average of β as a function of days from the last major change in control value.

map stringency level p to transmission rate β are depicted in Figures 6 and 7 respectively. There are clearly a few outliers which are left for discussion, but the overall behaviour is remarkable.

5. Discussion

One of the most important results from Tables 2 and 3 is that, for the bulk of countries and US States, the intervention leverage $\alpha_s \approx 0.01$. It is remarkable that this occurs whilst other parameters are measured to have a great variety, especially β_0 . This striking result also speaks to the universal character of the stringency index used here to quantify NPIs. The next most important result is the universal time domain response of the transmission rate, β to a change in stringency of control as depicted in Figure 5. The ensemble averages of β and p produce a very clear exponential decay to enhanced control which is well modeled by the kernel function proposed in eq. (1). For visual confirmation, a representative sample of countries are depicted in Figure 8.

5.1. Predictive capabilities of the model

The recent few weeks of extreme containment measures across the world have yielded valuable data to allow for country-specific predictions. With respect to transmission rate, our model can answer *how much?* change we can expect to see and *by when?* we expect to see it as function of p ; as seen in eq. (5). This was derived using eqs. (1) and (2). Hence,

$$\beta(t, p) = \beta_f - (1 + e^{-b_r t})\beta_0\alpha_s\Delta p, \quad (5)$$

Figure 6: Control surfaces of the model on observed transmission rate and stringency index for ensemble of countries within the study.

where $t = 0$ corresponds to the end of the lockdown period and the enacting of new interventions, such that $p < p_{max}$. The next few weeks of post-lockdown actions by a number of countries and states may refute this model and should be watched with interest.

5.2. Predictions for Italy

For illustration purposes, we choose the configuration of parameters obtained with Italian data, where $\phi = 0.1$ is used (see Section 3.2). The scenario considered here assumes that variations of the index occur after the last available data with $\Delta p = -10, -30$.

Figure 9 depicts the time dependence of the number of symptomatic population, the active cases and the cumulative number of cases and fatalities. One can appreciate that going from $\Delta p = -10$ to $\Delta p = -30$ has serious consequences in terms of the time it takes to achieve the peak in active case as well as the amplitude of the peak.

This is further illustrated in Figure 10, where the number of active cases and daily fatalities are shown as a function of time for different Δp ranging from -10 to -50. The time required for the peak to occur would go from over

Table 3: Results for various representative states within the United States of America. Results are given in terms of γ_0 , d_0 , β_0 , b_r^{-1} , p_{max} and α_s (see text). Parameters have been obtained with data up until April 26 2020.

259 six months to about four and the amplitude of the peak would double for a
 260 relaxation of $\Delta p = -20$ instead of $\Delta p = -10$. The uncertainty envelope in
 261 these predictions is driven primarily by the ensemble variation of α_s , which
 262 is of order of 10%. This is considered to be a more realistic estimate of the
 263 potential deviation from the linear behavior assumed in eq. (2). The other
 264 source of uncertainty is the daily recovery, γ , which is much smaller. Graphs

Figure 7: Control surfaces of the model on observed transmission rate and stringency index for ensemble of states within the United States.

in Figure 9 display the bands that incorporate these uncertainties.

Figures 9 and 10 predict that releasing containment measures too swiftly would lead to the resurgence of very large peaks of symptomatic infections within a month or two, leading to even worse outcomes compared to those observed so far.

5.3. Main synthesis: acceptable NPI control levels

Our entire synthesis regarding the value of NPIs as a measure of control of the current pandemic is captured by Figure 11. Once you define the concept of *criticality*, this synthesis follows by deduction.

Definition: Criticality is the allowable daily transmission rate, given the current daily recovery rate and daily death rate such that some constraint is almost, but not quite, violated.

For illustration, consider the constraint of keeping peak active cases below a threshold to prevent the country's health care system from being overwhelmed. There exists a critical line in the control surface of Figure 11, for

Figure 8: Representative sample of transmission rates in response to NPIs for countries. The exponential kernel in the response (black) to change in NPI (red) is clearly evident in all of these.

a given $\gamma + \delta$, that achieves this uniquely for that locale.

It is a very general principle, that the critical line is raised as the susceptible population is reduced in number. The full non-linear model in eq. (C.1) demonstrates this, as fewer and fewer people are susceptible the lower the need for NPIs to remain sub-critical.

If the desire is to relax NPIs below the current critical NPI level, p_c ; the only other degree of freedom left is the intervention leverage α_s which will need to be closely monitored. Outlier locales in Tables 2 and 3 have demonstrated that this is possible.

5.4. Monitoring intervention leverage is important

It is paramount to closely monitor the evolution of intervention leverage α_s as NPIs are released. If the clinical situation does not change, γ and δ will remain small. The allowable transmission rates will also have to remain small as well and therefore strict measures of NPIs will need to remain in place.

It is essential to increase α_s if the desire is to relax NPIs beyond the current critical NPI level, p_c in Figure 11. By increasing α_s , the critical NPI level is 'left shifted' and allows for an even greater relaxation of NPIs than would otherwise be possible. For the system to remain sub-critical, the rate with which α_s increases should outpace that of the decrease of the stringency index if a total relaxation of NPIs is desired. Monitoring of α_s becomes essential

Figure 9: Post-lockdown scenarios for Italy for $p = 85$ (upper plot), $p = 65$ (lower plot). Results are given using $\phi = 0.1$ of the susceptible population population, or vulnerable population, active cases and the cumulative distribution of total cases and fatalities. The bands correspond to the uncertainties in the model (see text).

to controlling the post-lockdown phase when controlled in this regime. For further details, see Appendix E.

5.5. Easier compliance with softer NPIs

One is tempted to speculate about the possibility of non-linear behavior in Eq. 2, where data would favor α_s to increase as p decreases i.e. it would be easier for citizens to comply with less stringent NPIs. This would be good news in terms of the effort required to manage the pandemic in that the

Figure 10: Number of active cases and new fatalities as a function for time for Italy by assuming different values of Δp ranging from -10 to -50. Results are computed with $\phi = 0.1$.

effectiveness of containment measures could increase as p decreases. This argument is hindered by the fact that the lapse of time between changes in the observed non-pharmaceutical interventions was not significant and measuring the effect of each individual intervention was therefore difficult. As a result of swift action by Governments, we observe the effect of an ensemble of more or less stringent measures, as opposed to their sequential application. To this end, we lack the evidence that would support the above mentioned non-linear behavior.

Figure 11: The constraints on the NPI control surface as it relates to the transmission rate. The intervention leverage, α_s affects how easy it is for a country to reduce transmission rate for a given stringency index level. There is a linearly stable zone, meaning that the observed daily transmission rate is less than the combined daily recovery γ and daily death rate δ i.e. $R_t < 1$. By definition, the critical level of NPI p_c may not be reduced further or there will be a guarantee of overwhelming the healthcare system. Note that the critical line moves upward as the size of the susceptible population decreases.

Locale	p_{max}	α_s	No. cities pop. greater than 1M
Arizona	62	0.014	1 (Phoenix, 1.6M)
North Dakota	48	0.018	0
Utah	62	0.015	0
Sweden	52	0.019	1 (Stockholm, 1.6M)
Switzerland	81	0.012	0

Table 4: Locales with relatively large α_s values and low p_{max} relative to other states and counties in the study set.

320 5.6. Insights from Outliers

321 It is appropriate to comment on some of the outliers identified in the
322 estimation of intervention leverage α_s . Table 4 summarises this discussion;
323 density of people plays a key role in intervention leverage and a correlation
324 study with World Bank data substantiates this claim further (See Appendix
325 D for further details). It need not be ignored that the prolonged spread of the
326 virus during the early stages of the pandemic in Italy and Spain were driven
327 by lack homogeneity in the adherence to advisories. This prompted govern-
328 ments to introduce severe restrictions to movement, where law enforcement
329 agencies became heavily involved in ensuring compliance. The importance
330 of public awareness and compliance with regards to NPIs to slow the spread
331 is hence embodied by the intervention leverage α_s and is an important ob-
332 servable during the post-lockdown stage.

333 5.7. Recommendations

334 A world wide survey paper is intended to follow our results where the key
335 parameters of our latent SIRD model are correlated with macro-economic,
336 public health and geo-physical measurements to determine the environmental
337 effects on the transmission, recovery and mortality parameters of COVID19.
338 While lockdown measures have been successful in curbing the spread, our
339 study indicates that removing them too swiftly will result in the resurgence
340 of the spread within one to two months. Reducing the stringency index by 10
341 will delay reaching the apex by about 6 months, where reducing it by 20 will
342 delay by only four. The peak cases almost double by moving from $\Delta p = -10$
343 to $\Delta p = -20$. This indicates that post-lockdown measures should be staged
344 and the reduction of the stringency index should be slow.

Appendix A. Stringency Index for United States of America

For each policy response measure S1-S7, OxCGRT use the ordinal value
(and add one if the policy is general rather than targeted). This creates a
score between 0 and 2 and for S5, and 0 and 3 for the other six responses²⁹.

The OxCGRT stringency index is given by:

$$p = \frac{1}{7} \sum_{J=1}^7 p_J, \quad (\text{A.1})$$

where p_J is defined by:

$$p_J = \frac{S_J + G_J}{N_J + 1}, \quad (\text{A.2})$$

with $G_J = 1$ if the effect is general (and 0 otherwise), and N_J is the cardinal-
ity of the intervention measure^{29,30}. In the case where there is no requirement

of general vs. targeted (S7), the +1 in the denominator and the G_J in the numerator are omitted from the equation to form:

$$p_7 = \frac{S_7}{N_7}, \quad (\text{A.3})$$

The OxCGRT database contains data for 133 countries however it does not contain specific data for US states. It is important to be able to compare the US states non-pharmaceutical interventions (NPIs) with those of other countries around the World in a unified framework.

To this end, we coded the known levels of intervention in America to match as nearly as possible, the OxCGRT system. We used the Institute for Health Metrics and Evaluation (IHME) dashboard to obtain six dates at which specific states imposed different NPIs³¹.

Label	NPI
$U1$:	Stay at Home Order
$U2$:	Educational Facilities Closed
$U3$:	Non-essential Services Closed
$U4$:	Travel Severely Limited
$U5$:	Initial Workplace Closure
$U6$:	Banned Mass Gatherings

Table A.5: Table Showing US Interventions Acquired from the IHME.

In order to compare the US intervention data it was necessary to make a stringency index for the US states that mimics that of the index that was made for the World data by OxCGRT.

The following decisions were made during the process of mapping the reported US NPIs to the OxCGRT index:

- The US *Mass Gatherings Banned* $U5$ can be mapped directly to the Oxford *Cancel Public Events* $S3$.
- The US *Initial Business Closure* $U6$ can be mapped to the Oxford *Work Place Closure* $S2$

- 397 • The US *Travel Severely Limited* U_4 can be mapped to the Oxford *Do-*
398 *mestic Travel Bans* S_6 and *International Travel Bans* S_7 combined.

Label	Interventions Not Directly Interchangeable
US NPIs:	
U_1 :	Stay at Home Order
U_3 :	Non-essential Services Closed
OxCGRT NPIs:	
S_4 :	Close Public Transport
S_5 :	Public Information Campaign

Table A.6: Table Showing Unmapped NPIs.

399 Although some of the above US interventions were not directly compa-
400 rable to the OxCGRT indicators, their individual impact on the stringency
401 index is still valid and should be included in the index. By including U_1 and
402 U_3 with the appropriate weight into the same calculation OxCGRT used for
403 their index, an equivalent US index is created. The following equation was
404 developed:

$$p = \frac{1}{7}(1(v_1) + 1(v_2) + 1(v_3) + 2(v_4) + 1(v_5) + 1(v_6)), \quad (\text{A.4})$$

405 where v_i is a number out of 100 indicating the extent each of the inter-
406 ventions are imposed.

407
408 Due to lack of data on the *Travel Severely Limited* intervention in the
409 IHME database. It was necessary to source US travel restrictions information
410 from other US news sources. There have been a number of travel interven-
411 tions that have been implemented however there have not been widespread
412 travel bans between states.³² The first significant travel restriction was a
413 US-Europe travel ban to 26 European countries, which was announced on
414 11 March 2020.³³ On 19 March 2020 the US issued a level 4 "Do not travel"
415 advisory which is the highest travel restriction in the US. US citizens were
416 informed that they can travel back to the US if they were out of the country
417 when the ban was announced but if they do not do so timely they might find
418 themselves having to stay abroad for an extended period of time. Foreign
419 nationals who have been to the 26 EU countries or the UK, China, Iran or
420 Ireland are not allowed entrance to the US.³⁴ In terms of the interstate travel

421 restrictions. There have been no full travel bans but in some states you are
 422 required to quarantine for 14 days after arrival.³² Therefore, it was necessary
 423 to introduce a leveled implementation of the U4 *Travel Severely Restricted*
 424 measure. Using the same logic used by the Oxford COVID-19 Government
 425 Response Tracker (OxCGRT) the following equation for v_i was introduced:

$$v_i = 100 \frac{U_i}{N_i}, \quad (\text{A.5})$$

426 where U_i is ordinal and can vary from 0 to the cardinality of the inter-
 427 vention measure, N_i . This is for the purpose of incorporating levels of imple-
 428 mentation of specific interventions into the stringency calculation. Based on
 429 the data the only intervention that requires levels of implementation is the
 430 U_4 intervention.

431 The following ordinal levels were employed for U_4 :

- 432 0. No travel restrictions (US before the 11 March 2020)
- 433
- 434 1. US preliminary travel ban to 26 EU Countries (Commenced 11 March
- 435 2020)
- 436
- 437 2. Level 4 “Do not travel” advisory issued (19 March 2020)
- 438
- 439 3. Interstate Travel bans (No interstate travel bans are currently imposed)
- 440

441 The specification for comparable p among countries within the OxCGRT
 442 database and the United States of America is completed with the above
 443 definitions.

444 **Appendix B. Model Details**

445 An explanation of the model is warranted. It has a causal structure and
 446 may be clinically interpreted as well, both of which are desirable properties
 447 for a model which needs to be controlled. The causal structure gives insight
 448 into *what* to control and the clinical interpretation gives insights into *how*.

449
 450 **Susceptible individuals, S** : These are the unexposed and suscepti-
 451 ble individuals within the population and include healthcare workers as well

general members of the public.

Observed infections, I : These infections represent patients who have tested positive for COVID-19 and are actively reported on¹⁰. Any contacts of these patients who subsequently test positive, any nosocomial infections due to these patients (for example, healthcare workers who contract the disease) or any other individuals who knowingly interact with COVID-19 positive patients are modeled by β , the transmission rate of COVID-19 amongst observed infections. Well prepared countries with strict healthcare protocols for known positive patients, for example quarantining, effective use of personal protective equipment for healthcare providers, and physically separate care pathways for positive patients all essentially work to ensure that β is kept as small as possible.

Asymptomatic also transmissible Some of these observed infections, I are due to some mild or asymptomatic cases which become severe enough to warrant testing or cause patients to seek medical attention. These cases are modeled by ϕI_L , where ϕ is dependent on the probability that a latent infection I_L becomes a known positive case, I . Latent infections are addressed next.

Latent infections, I_L : There is evidence of a non-trivial fraction of cases going undetected as a result of presenting with mild symptoms or being asymptomatic^{35,36}. This is the reason for including the latent variable dynamics within our modification of the standard SIRD model.

Table 1 in the main text has good estimates of asymptomatic cases; together with the patients who have subclinical manifestations of Covid-19, these cases are all included in the latent infection group, I_L .

It is the susceptible group's interaction with these asymptomatic and mild cases which produce new latent infections and this is modeled through β_L , the non-negligible latent transmission rate.

Latent recoveries, R_L : A majority of these asymptomatic and mild symptom patients resolve the virus using their natural immunity without ever being tested. Early reports indicate that this may be a substantial number of latent infections^{16,18}. These cases eventually form part of the latent recovered group, R_L . The rate of recovery of the latent infected group is captured by γ_L .

Latent infections dying, $\delta_L I_L$: These counts are considered weakly ob-

servable and rare. The weak observability is present with the revised, erratic death counts by some officials when home visits uncover additional cases¹⁰. It is unclear that these may be directly attributable to the virus in that confirmation would be required via post-mortem COVID-19 testing[?]. Given the existing testing burden posed on most countries, this sort of testing is rare and, therefore, the uncertainty in this parameter will remain high¹⁸.

Known recoveries, R : These are patients who are known to test positive for COVID-19 and are known to have recovered fully from the virus. The recovery rate, γ , models how quickly known infections are resolved and discharged out of the healthcare system. This rate is physically dependent on treatment regime and the patient's own physical condition.

Deceased patients, D : The number of deceased individuals is denoted by D ; and it is mostly affected by the known individuals who have tested positive and are currently being treated in the prevailing healthcare system. The implications for the model are that $\delta \gg \delta_L$ i.e. under normal treatment and monitoring situations, the implied probability of fatality for a known infection is much larger than the implied probability of fatality for a latent infection.

Under the above conditions, the model explicitly caters explicitly for the situation that the latent infections are asymptomatic or mild.

It is trivial to show that $S + I + I_L + R_L + R + D = N$ at every instant in time. Furthermore, the model in Figure 1 implies that:

$$\frac{dS}{dt} = -\beta_L \frac{S I_L}{N}, \quad (\text{B.1})$$

$$\frac{dI_L}{dt} = \beta_L \frac{S I_L}{N} - \phi I_L - \gamma_L I_L, \quad (\text{B.2})$$

$$\frac{dI}{dt} = \phi I_L - \delta I - \gamma I, \quad (\text{B.3})$$

$$\frac{dR}{dt} = \gamma I, \quad (\text{B.4})$$

$$\frac{dD}{dt} = \delta I. \quad (\text{B.5})$$

514 *Appendix B.1. Linearisation*

515 Each of the equations in (B.1) - (B.5) were linearised using the approx-
516 imation that $S = N - \epsilon$, which gives equivalent results to the Jacobian
517 method²⁷. This operating point corresponds to the case where the epidemic
518 is still in the early/controllable phase and the number of infected individuals
519 is small compared with the size of the total population N .

520 The derivatives with respect to time were approximated using first order
521 backward difference approximations at a daily level. Classical frequentist er-
522 ror propagation was applied to this linear approximation using the Gaussian
523 process assumption.

524 Theoretically, these approximations are valid provided that:

- 525 1. the number of infected are a small fraction of the susceptible popula-
526 tion.
- 527
- 528 2. the dynamics of the disease process are slow compared with a single
529 day. This is justified by the work from Weiss and Murdoch³⁶.
- 530

531 The final form, used for analysis of the time variation of the parameters
532 as various forms of control are applied is:

$$\gamma(t) = \frac{\Delta R}{I[t-1]} \pm \sigma_\gamma(t), \quad (\text{B.6})$$

$$\delta(t) = \frac{\Delta D}{I[t-1]} \pm \sigma_\delta(t), \quad (\text{B.7})$$

$$\beta(t) = \frac{\Delta R + \Delta D + \Delta I}{I[t-1]} \pm \sigma_\beta(t), \quad (\text{B.8})$$

533 where $\sigma_x(t)$ is the noise estimate at day t , $\Delta x := x[t] - x[t-1]$ and x is
534 either R , D or I .

535 *Appendix B.2. Error propagation*

536 Using the coefficient of variation and propagating the error in the linear
537 approximation, assuming that the errors in the daily counts are within 10%³⁷,
538 the probable noise levels in the daily time variations are calculated by:

$$\sigma_\gamma(t) = \gamma(t) \sqrt{\frac{1}{\Delta R} + \frac{1}{I[t-1]}}, \quad (\text{B.9})$$

$$\sigma_{\beta}(t) = \beta(t) \sqrt{\frac{1}{\Delta R + \Delta I + \Delta D} + \frac{1}{I[t-1]}}, \quad (\text{B.10})$$

539 and

$$\sigma_{\delta}(t) = \delta(t) \sqrt{\frac{1}{\Delta D} + \frac{1}{I[t-1]}}. \quad (\text{B.11})$$

540 These results depend on the count data being Poisson processes and the fact
 541 that the coefficient of variation of a Poisson process is $\lambda^{-1/2}$. Recall that the
 542 general coefficient of variation of a division of two random variables is the
 543 quadrature sum of the numerator and denominator coefficients of variation;
 544 the results follow³⁷.

545 *Appendix B.3. Details of Linearisation*

546 If dt is taken as one day, t is the day index and $\Delta x = x[t] - x[t-1]$, then
 547 with the modeling assumptions the differential equations simplify to:

$$\Delta S = -\beta_L I_L[t-1], \quad (\text{B.12})$$

$$\Delta I_L = (\beta_L - \gamma_L - \phi) I_L[t-1], \quad (\text{B.13})$$

$$\Delta I = \phi I_L[t-1] - \gamma I[t-1] - \delta I[t-1], \quad (\text{B.14})$$

$$\Delta R = \gamma I[t-1], \quad (\text{B.15})$$

$$\Delta D = \delta I[t-1]. \quad (\text{B.16})$$

548 Use of (B.15) and (B.16) yield the daily estimates of the observable recovery
 549 rate, γ and fatality rate δ . Combining (B.15), (B.16) and (B.14) give the
 550 daily estimate of the transmission rate, as observed through the detection
 551 efficiency.

552 Appendix C. Control Dynamics

553 Efforts to control the pandemic do not happen everywhere, all at once and
554 this is the reason that the control efforts can be said to be dynamic. Indeed,
555 the form of the kernel functions in equations (1) - (4) state this implicitly.
556 Each of the observed parameters will be looked at it in this section and their
557 dynamics described. These forms have non-trivial implications for control of
558 the pandemic and will be expounded upon in a follow up paper.

559 Transmission rate

560 The beta kernel in (1) and the steady state behaviour modeled by (2) imply
561 that the transmission dynamics, under stringency of control p , behave as a
562 first order control system²⁷:

$$b_r \frac{d\beta}{dt} = \beta_0 - \beta(t) - \beta_0 \alpha_s p, \quad (C.1)$$

563 where b_r is the typical adjustment time for a control measure to take full
564 effect, α_s is the societal sensitivity (estimated for each country in our work)
565 to control measures $p \in [0, 100]$, and β_0 is the uncontrolled transmission rate
566 within a society.

567 As a sense check; when $p = 0$ then the equilibrium condition of (C.1) is found
568 by solving (C.1) with $\beta(t) = \beta_f = \text{const}$. The non-trivial solution is $\beta_f = \beta_0$
569 and shows that, without control, the transmission rate becomes β_0 . This is
570 defined as the uncontrolled transmission rate and is as it should be.

571 If $p \neq 0$, then the equilibrium condition is $\beta_f = \beta_0 - \beta_0 \alpha_s p$ which is exactly
572 equation (2). The general analytic solution to (C.1) is precisely the kernel
573 function in (1).

574

575 It is this form which allows for the use of classic and modern control
576 methods to shape $\beta(t)$ to a form that is acceptable for the desired goals of
577 the pandemic control system eg. minimise total deaths, minimise the peak
578 load on the health care system, maximise the economic activity etc. These
579 aspects will be dealt with in detail in a follow up paper.

580 Appendix D. Correlation of transmission rate with macroscopic 581 indexes

582 The phases of the spread and its parameters bear strong similarities in a
583 wide range of countries considered here. However, non-trivial differences in

584 terms of parameters can be observed when scrutinising country by country
585 variations. It is relevant to correlate variances with respect to macroscopic
586 indexes. For this purpose the number positive cases is analysed as a function
587 of time using the parametric expression:

$$I(t) = \frac{I_{tot}}{1 + e^{-\xi_I(t-C)}}, \quad (D.1)$$

588 where I_{tot} denotes the total expected number of positive cases for $t \rightarrow \infty$,
589 ξ_I is the slope of the exponential growth that characterises the first phase
590 of the spread, and C can be interpreted as a measure of the time needed to
591 deviate from the initial exponential growth leading to containment. Time is
592 expressed in number of days. A total number of 67 countries are selected,
593 where containment measures have proven effective in curbing the spread.
594 These include countries in all continents and with a wide span in terms of
595 socio-economic development, inequality and population density.

596 Macroscopic indicators are organised according to relevant themes: socio-
597 economic vulnerabilities, demographics, social expenditures and aggregate
598 economic indicators. A total of 34 indicators from the World Bank data base
599 are selected and are correlated with the parameter ξ_I from each country.

600 The Gini index quantifies the extent to which the distribution of income
601 among individuals or households deviates from perfect equality. The selected
602 sample of countries displays a minimum and a maximum Gini index of 24 and
603 50, respectively. It is found that the parameter ξ_I is almost insensitive to the
604 Gini index. This is illustrated in Figure D.12 where the red line corresponds
605 to a first order polynomial that is consistent with zero slope. In order to
606 exclude statistical fluctuations in the sample a similar study is performed
607 using the percentage share of income held by the lowest 10% and 20% of the
608 income bracket. No significant correlation is found for either of the indexes.
609 This indicates that social inequality is not strongly correlated with the rate
610 of spread of the virus.

611 This observation is further strengthened by evaluating the correlation
612 with the proportion of the urban population living in slum households. Ac-
613 cording to the World Bank, a slum household is defined as a group of in-
614 dividuals living under the same roof lacking one or more of the following
615 conditions: access to improved water, access to improved sanitation, suffi-
616 cient living area, and durability of housing. Out of the 67 countries under
617 scrutiny, 18 report a significant fraction of urban population living in slums.
618 In this sample of countries the fraction ranges from 8% to 53%. No signifi-

Figure D.12: Correlation of ξ_I (see text) with the Gini index (left) and the population in urban agglomerations of more than one million to the country's population living in metropolitan areas (right). The red lines correspond to first order polynomials that illustrate the degree of correlation.

619 cant correlation is found between this index and ξ_I . In addition, the average
620 value of ξ_I for these 18 countries is compatible with that of the rest of the
621 ensemble studied.

622 As per the physical picture underlying the model used to describe the
623 spread, it is expected that population density should play a significant role.
624 No significant correlation is found with the average population density. This
625 can be explained by the fact that the average population density is not neces-
626 sarily a good metric for population density in urban areas, where the spread
627 is most likely to occur. It should be noted that the correlation with the frac-
628 tion of the population in urban areas is not statistically significant. In order
629 to scrutinise the relevance of localised population density, the index made
630 of the population in urban agglomerations of more than one million to the
631 country's population living in metropolitan areas in percentiles is used, as il-
632 lustrated in Figure D.12. It is found that the correlation can be parametrised
633 with a first order polynomial with a slope of $(1 \pm 0.3) \cdot 10^{-3}$ per day. The
634 significance of the correlation greater than a 3σ Confidence Level. This the
635 most significant correlation out of all the indexes considered here.

636 Appendix E. Inequality for relaxing beyond the critical NPI level

637 It will be argued that one of the strategies for the post-lockdown period
638 is to increase intervention leverage α_s as p decreases. This will sustain quasi-
639 linear behavior in the number of active cases and it is depicted in Figures 9

640 and 10 for $\Delta p = -10$.

641 In practice, all relevant parameters that enter the temporal evolution de-
642 scribed above need to be tuned such that the expected peak of the number of
643 cases and ICU usage falls below the thresholds characteristic to each coun-
644 try. One can denote a vector of critical parameters for which a country's
645 healthcare system is not overwhelmed:

$$\vec{v}_c(t) = (\gamma_c, d_c, \beta_c, \alpha_s^c). \quad (\text{E.1})$$

646 This is what is meant by *criticality*; the value of parameters such that the
647 healthcare system is only marginally not overwhelmed. One can assume that
648 γ_c and δ_c display a weak time dependence in that they primarily depend on
649 medical advances, rather than on NPIs. In this setup the condition for the
650 system to remain sub-critical can be expressed as follows:

$$\left. \frac{\partial \alpha_s}{\partial t} \right|_c \geq - \left. \frac{\partial p}{\partial t} \right|_c, \quad (\text{E.2})$$

651 where the temporal partial derivatives are evaluated at the point of criticality
652 defined by $\vec{v}_c(t)$. The inequality (E.2), while seemingly straightforward from
653 a mathematical standpoint, has serious consequences for policy makers.

654 While lockdown measures have been successful in bringing the reproductive
655 factor down to one and below, it is evident that these are having devastating
656 effects on the economic landscape. In African countries, lockdown measures
657 necessary to control the epidemic are leading to widespread malnutrition in
658 vast sections of the population.

659 On the other hand, the illustrative example shown in Section 5.1, indicates
660 that for fixed intervention leverage α_s , reducing p significantly can lead to
661 the advent of an epidemic of unprecedented proportions. Under these con-
662 ditions, the inequality (E.2) speaks to the need to ensure that the rate with
663 which intervention leverage α_s grows should outpace that of easing non-
664 pharmaceutical interventions.
