Objective: Our intention was to compare the pregnancy safety in women with hyperthyroidism seeking future pregnancy after ATD, RAI or thyroidectomy treatment and to explore the optimum treatment strategy. We hope the results will guide the choice for endocrinologists and patients, and be beneficial for promoting eugenics.

Methods: We searched multiple databases though December 2019. The outcome indicators were abortion, preterm birth, IUGR and birth defect. We conducted a frequency-framework network meta-analysis by using Stata and R software. The

results of the intervention comparison were expressed as OR with 95%CI, and ranking was assessed using surface under the cumulative ranking (SUCRA) probabilities.

Results: The network meta-analysis included 4 retrospective cohort studies with a total enrollment of 480 patients. ①Thyroidectomy had a lower risk of abortion than RAI [OR=0.77, 95%CI (0.23, 2.56)] and ATD [OR=0.68, 95%CI (0.21, 2.21)]. RAI had a lower risk of abortion than ATD [OR=0.88, 95%CI (0.45, 1.75)]. Based on SUCRA results, thyroidectomy (0.698) was followed by RAI (0.494), ATD (0.308). Thyroidectomy (60.7%) had the highest probability of being first compared to RAI (27.0%) and ATD (12.4%). ②Thyroidectomy had a lower risk of preterm birth than RAI [OR=0.80, 95%CI (0.26, 2.44)] and ATD [OR=0.79, 95%CI (0.39, 1.59)]. RAI had a lower risk of preterm birth than ATD [OR=0.98, 95%CI (0.42, 2.33)]. Based on SUCRA results, thyroidectomy (0.703) was followed by RAI (0.430), ATD (0.367). Thyroidectomy (57.8%) had the highest probability of being first compared with RAI (30.5%) and ATD (11.8%). ③Thyroidectomy had a lower risk of IUGR than RAI [OR=0.28, 95%CI (0.03, 3.02)] and ATD [OR=0.83, 95%CI (0.14, 4.86)]. RAI had a higher risk of IUGR than ATD [OR=3.02, 95%CI (0.60, 15.27)]. Based on SUCRA results, thyroidectomy (0.717) was followed by ATD (0.663), RAI (0.120). Thyroidectomy (56.6%) had the highest probability of being first compared with RAI (5.4%) and ATD (37.9%). ④Thyroidectomy had a lower risk of birth defect than RAI [OR=0.70, 95%CI (0.02, 30.34)] and ATD [OR=0.23, 95%CI (0.01, 4.52)]. RAI had a lower risk of birth defect than ATD [OR=0.32, 95%CI (0.03, 3.12)] (Table 2). Based on SUCRA results, thyroidectomy (0.70) was followed by RAI (0.629), ATD (0.171). Thyroidectomy (55.9%) had the highest probability of being first compared with RAI (41.3%) and ATD (2.8%).

Conclusion: Thyroidectomy was the optimum option for women with hyperthyroidism seeking near future pregnancy. The future research direction is to include more samples to conduct head-to-head randomized controlled trials or

prospective cohort studies, establish inclusion criteria for various pre-pregnancy conditions or further subgroup analysis, and develop more acceptable, safer, and more manageable treatments that allow for the remission of both thyroid function and autoimmune abnormalities.

key words: hyperthyroidism, women of childbearing age, therapy, pregnancy outcome, network meta-analysis

Introduction

Hyperthyroidism is common in women of childbearing age^[1]. The main treatment options for them are antithyroid drugs (ATD), radioactive iodine (RAI) and thyroidectomy. The pregnant safety after different therapies for hyperthyroidism in a patient planning pregnancy is of great concern. However, the relevant guidelines of the Chinese Medical Association Endocrine Society, the European Thyroid Association (ETA) and the American Thyroid Association (ATA) all hold that each therapeutic option carries advantages and disadvantages^[2,3], so it is not clear which is the safer option. The early documented surveys showed that clinical endocrinologists from different countries had significantly different clinical practice patterns in the management of a hyperthyroid woman planning pregnancy over the next 6-12 months (the index case). Thyroidectomy is more frequently suggested in Italy than in the EU and USA (Italy: thyroidectomy 54.3%, ATD 36%, RAI 9.7%; EU: ATD 59.3%, thyroidectomy 30.3%, RAI 10.4%; USA: ATD 49.9%, RAI 29.8%, thyroidectomy 20.3%)^[4-6]. Furthermore, to date, there are no head-to-head trials, and there are few or no pairwise comparative study answering the question. Therefore, in this study, we aimed to do a network meta-analysis to inform clinical practice by comparing the risk of adverse pregnancy outcomes including abortion, premature delivery, intrauterine growth restriction (IUGR) and birth defect.

Materials and Methods

Study eligibility

We involved women of childbearing age (20-40y) who were conformed hyperthyroidism and were pregnant after treatment for hyperthyroidism. There were no restrictions on the single, twin or multiple pregnancies. The time interval from treatment to pregnancy was also not limited, except treatment with RAI should be delayed at least 6 months. We did not restrict whether the patient reached a stable euthyroid state before conception. The publications should compare treatments with at least two of the three interventions: ATD (MMI, CMZ, PTU), RAI and thyroidectomy. ATD dose, ATD treatment duration, RAI dose, number of RAI treatments, the extent of thyroidectomy was not restricted. The outcomes were the rate of abortion, premature delivery, IUGR and birth defect. Studies were included in this study were randomized clinical trials (RCTs) and observational cohort studies. There was no language and country restrictions.

Data sources and search strategies

We searched PubMed, Cochrane Library, Embase and CNKI databases from database inception to December 2019. We searched MeSH terms “hyperthyroidism”, “antithyroid agents”, “Methimazole”, “Carbimazole”, “Propylthiouracil”, “radiotherapy”, “thyroidectomy”, “pregnancy”, and “female” with the corresponding free words.

Study selection and data extraction

Two investigators independently selected eligible studies according to titles, abstracts, and full texts, and extracted the relevant information from the included studies. A form was used to extract the following information: author, data of publication, countries, publication type, the data collection time, sample size, type of treatment, dose and treatment duration of ATD, dose and numbers of RAI, the extent of thyroidectomy (total or subtotal thyroidectomy), the time interval from treatment to pregnancy, mean age, type of hyperthyroidism, disease course, thyroid function and TSH receptor antibodies (TRAb) levels before and during conception, different drugs used during pregnancy, follow-up duration, the number of patients with outcomes.

Quality assessment

Two investigators independently assessed the risk of bias. The Cochrane collaboration's risk of bias assessment tool was used for RCTs, and the Newcastle-Ottawa scale (NOS) was used for cohort studies.

Data analysis

We used Stata (version 16) and R (version 3.5.1) software to do a frequency-framework network meta-analysis. We assessed the heterogeneity for all comparisons using the I^2 statistic. Consistency between direct and indirect sources of evidence was assessed globally and locally in the closed loops. If at least ten studies were included, we used the funnel plot and Egger's test to analysis publication bias. The effect estimates were expressed as odds ratio (OR) with 95% confidence interval (95%CI), and the ranking of treatments was assessed using surface under the cumulative ranking (SUCRA) probabilities.

Results

We identified 6 eligible articles, and 2 articles were excluded because the author couldn't be contacted for complete data^[7, 8]. Overall, 4 cohort studies published between 2014 and 2018 were included in the meta-analysis: 3 English articles were from PubMed database^[9-11] and 1 Chinese article was from CNKI database^[12] (Figure1). These studies involved a total of 480 patients (234 in the ATD group, 147 in the RAI group, 99 in the surgical group). In the surgical group, there were 78% had been performed with subtotal thyroidectomy and 22% had been performed with total thyroidectomy prior to pregnancy. About mean age of the included patients, in the ATD group, 75% of them were 29 years old, and 25% were 26.8±3.5 years old; in the RAI group, 88% of them were 29 years old, and 12% were 31 years old; in the surgery group, 29% of patients were 29 years old, 59% were 26.2±3.4 years old, and 12% were 28 years old. In terms of the mean time interval from treatment to pregnancy, 54% of patients in the ATD group were at least 6 months apart, and 46% were not reported; in the RAI group, 88% of patients had an interval of at least 6 months, and 12% were 32 months (rang, 0.5-96.2 months) apart; in the surgery group,

29% of patients were 3 years (rang, 0-9 years) apart, 12% were 19.6 months (rang, 3-113.1 months) apart, and 59% did not report. In the ATD group, 56% of the patients took ATD or L-T4 during pregnancy, 20% stopped taking medicine, and 24% was not reported; in the RAI group, 82% of the patients took PTU or L-T4 during pregnancy, 18% stopped taking the medicine; in all the surgical group, drugs used during pregnancy were not reported. In regards to thyroid function during pregnancy, in the ATD group, 54% of the included patients had stable thyroid function, and 46% were not reported; in the RAI group, 88% of the patients had stable thyroid function; in the surgical group, 12% of the patients had stable thyroid function, and 56% did not report it. Mean follow-up duration was not clearly indicated. The 4 included articles all reported abortion rate, 3 articles reported premature delivery rate, 2 articles reported IUGR rate, and 2 articles reported birth defect rate. The studies were conducted in the following countries: China, 2; New Zealand, 1; France, 1 (Table 1). The methodological quality of included studies saw the Table 2.

Network analysis

Figure 2 shows the network plot of pregnancy outcomes including the rate of abortion (A), premature delivery (B), IUGR (C) and birth defect (D). In the analysis, the heterogeneity was all less than 25%, suggesting the low heterogeneity (Table 3). The inconsistency test of abortion wasn't found statistical difference, showing a good consistency (Figure3, Table 4).

Abortion

Thyroidectomy had a lower risk of abortion than RAI [OR=0.77, 95%CI (0.23, 2.56)] and ATD [OR=0.68, 95%CI (0.21, 2.21)]. RAI had a lower risk of abortion than ATD [OR=0.88, 95%CI (0.45, 1.75)] (Table 5). However, the statistical differences in the three treatments were not significant. Based on SUCRA, thyroidectomy (0.698) was ranked first, RAI treatment was second (0.494), ATD was the last (0.308). Thyroidectomy (60.7%) had the highest probability of being first compared to RAI (27.0%) and ATD (12.4%) (Figure 4A, Table 6).

Preterm birth

Thyroidectomy had a lower risk of preterm birth than RAI [OR=0.80, 95%CI (0.26, 2.44)] and ATD [OR=0.79, 95%CI (0.39, 1.59)]. RAI had a lower risk of preterm birth than ATD [OR=0.98, 95%CI (0.42, 2.33)] (Table 5). However, no statistical difference was found among the three groups. Based on SUCRA, thyroidectomy (0.703) was ranked first, RAI was second (0.430), ATD was the last (0.367). Thyroidectomy (57.8%) had the highest probability of being first compared with RAI (30.5%) and ATD (11.8%) (Figure 4B, Table 6).

IUGR

Thyroidectomy had a lower risk of IUGR than RAI [OR=0.28, 95%CI (0.03, 3.02)] and ATD [OR=0.83, 95%CI (0.14, 4.86)]. RAI had a higher risk of IUGR than ATD [OR=3.02, 95%CI (0.60, 15.27)] (Table 5). However, no statistical difference was found among the three groups. Based on SUCRA, thyroidectomy (0.717) was ranked first, ATD was second (0.663), RAI was the last (0.120). Thyroidectomy (56.6%) had the highest probability of being first compared with RAI (5.4%) and ATD (37.9%) (Figure 4C, Table 6).

Birth defect

Thyroidectomy had a lower risk of birth defect than RAI [OR=0.70, 95%CI (0.02, 30.34)] and ATD [OR=0.23, 95%CI (0.01, 4.52)]. RAI had a lower risk of birth defect than ATD [OR=0.32, 95%CI (0.03, 3.12)] (Table 5). However, no statistical difference was found among the three groups. Based on SUCRA, thyroidectomy (0.70) was ranked first, RAI was second (0.629), ATD was the last (0.171). Thyroidectomy (55.9%) had the highest probability of being first compared with RAI (41.3%) and ATD (2.8%) (Figure 4D, Table 6).

Discussion

We conducted a network meta-analysis of the pregnancy safety to determine the optimal treatment for hyperthyroidism in a patient planning pregnancy. In the risk of abortion, premature delivery, IUGR and birth defect, we found that thyroidectomy

was safer than RAI and ATD, and RAI were safer than ATD except for the IUGR. Assessing the above four adverse pregnancy outcomes comprehensively, the option of thyroidectomy was ranked first for women with hyperthyroidism seeking future pregnancy, RAI was second, and ATD was the last.

According to the available evidence, there may be the following reasons for the last rank of ATD in the above ranking. ATD is a risk factor of birth defect. PTU and MMI/CMZ equally cross the placenta^[13]. A Denmark national cohort study published in 2013 found that both the MMI/CMZ and PTU were associated with birth defect, but the spectrum of malformations differed^[14]. Moreover, birth defects could lead to an increase in preterm births. A study between 1995 and 2000 from 13 states showed that birth defects was more than twice among premature babies compared with full-term babies [PR=2.65, 95%CI (2.62, 2.68)]^[15]. However, a routine shift from MMI/CMZ to PTU in the early pregnancy couldn't reduce the risk of birth defect (PTU, 8.0%; MMI/CMZ, 9.1%; shift between MMI/CMZ and PTU, 10.1%; no ATD, 5.4%; nonexposed, 5.7%; $P < 0.001$)^[14]. In addition to the increased risk of birth defects, there are problems such as slowly achieving stable euthyroid state, high recurrence rate, long treatment time, and many side effects with ATD therapy. ATD therapy slowly achieving stable euthyroid state leads to women exposed to the risks of pregnancy complicated by hyperthyroidism and the increased need for ATD to control thyroid function during pregnancy. Mr. Hamburger et al. agreed that more aggressive initial therapy (RAI or thyroidectomy) rather than suppressive therapy (ATD) employed before pregnant could prevent pregnancies complicated by hyperthyroidism^[16]. The reported relapse rate was approximately 50-70%^[2, 17]. Many meta-analysis had confirmed the high relapse rate of ATD therapy in comparison with RAI and thyroidectomy^[18-20]. The common adverse effects, including rash, agranulocytosis, hepatic dysfunction, vasculitis, arthritis, were also ascribed to ATD^[21]. Furthermore, although ATD therapy could lead a fall in TRAb, the effect mainly lasted during the period of ATD administration. After drug withdraw, the abnormal autoimmunity was reactivated in 50% of the patients, resulting in an elevated or reappearance serum TRAb and the relapse of hyperthyroidism^[22]. Though

ATD is an easy oral administration and cheap, it's not the ideal choice for women with hyperthyroidism seeking future pregnancy.

The reasons why RAI is not the ideal intervention are as follows. TRAb is not easy to relieve after RAI treatment. A 5-year prospective randomized study in Denmark showed that serum TRAb gradually decreased and turned negative after 18 months in about 70-80% of the patients after ATD and thyroidectomy. However, for RAI treatment, the TRAb level deteriorated within 1 year and then began to decline in the following years, and the number of patients with TRAb negative conversion was significantly lower than ATD and thyroidectomy^[22]. The fetal thyroid gland has the function of secreting thyroid hormone from the 16-17 weeks of pregnancy. Maternal TRAb enters the fetal compartment through the placental barrier, which stimulates the fetal thyroid by binding to the TSH receptor, causing increased thyroid hormone secretion and hyperthyroidism in the fetus and newborn^[23]. Thyrotoxic fetuses may develop goiter, tachycardia, heart failure, growth retardation, craniosynostosis, increased fetal activity and accelerated bone maturation, leading to premature birth and high early mortality rate^[24, 25]. In addition, limited information is available on whether TRAb directly contributes to adverse pregnancy outcomes. It was reported that TRAb directly blocked the luteinizing hormone (LH) receptor on the corpus luteum, reducing progesterone secretion^[26]. Even if the patient's thyroid function is normal during pregnancy, high levels of TRAb can still lead to adverse pregnancy outcomes. Attention should be paid to monitoring TRAb and fetal growth during pregnancy. Whether RAI therapy for hyperthyroidism will increase genetic damage is also a common concern of many patients and doctors. Although most studies believed that there was no evidence that patients treated with RAI had a significantly increased risk of genetic damage^[27, 28]. The recurrence of hyperthyroidism after RAI treatment also requires attention. A large retrospective study with over 4 years of follow up showed that nearly 23% of patients relapsed after RAI treatment and needed a second RAI treatment or converted to surgical treatment^[29]. Laurberg et al. considered the possible teratogenic risks of ATD and the long-lasting TRAb after RAI treatment, suggesting that thyroidectomy was the best treatment option for hyperthyroidism

women of childbearing age^[30]. Although RAI is an easy oral administration and has rapid relief of thyroid function, it does not seem to be the best choice for hyperthyroidism in fertile women.

Davis et al. found that thyroidectomy for hyperthyroidism could restore euthyroid state faster than RAI [3 months (2-7 months) versus 9 months (4-14 months); $p < 0.001$]^[31]. A study showed that subtotal thyroidectomy was not an optimal surgical strategy for Graves' disease (GD) because the recurrence rate (28.7%) was high and the euthyroid rate was lower than total thyroidectomy^[32]. However, nearly 80% of the included surgical cases underwent subtotal thyroidectomy, and still had a good pregnancy outcome after surgery, probably because most of them had pregnancy before postoperative relapse. Though thyroidectomy is the safer option, it's not risks free. Surgical complications are a concern. The common complications are transient hypocalcemia and hoarseness, resolving within 6 months in most patients. The most feared complication is permanent recurrent laryngeal nerve injury (0-2%). Other possible complications include a low incidence of superior laryngeal nerve injury, postoperative bleeding, and the risk of anesthesia^[33]. In addition, after thyroidectomy, a few patients cannot achieve remission of autoimmune abnormality, causing hyperthyroidism in fetus and newborn during pregnancy^[34-36]. Therefore, women with hyperthyroidism treated with thyroidectomy, need to pay attention to monitoring not only thyroid function to prevent hypothyroidism, but also maternal TRAb and neonatal thyroid function during pregnancy.

Among the 4 outcome indicators, no statistical significance was found, which may be related to the small sample size. Although there was no statistical significance, we cannot ignore its clinical significance. Whether the difference is statistically significant or not, network meta-analysis can always give the optimal intervention measures. Statistics, of course, only gives us a trend, and we need to carefully verify in clinical practice.

This study included the patient with hyperthyroidism who had not achieved euthyroid state before pregnancy because considering the situation of the real-world population and the overall effect with therapies. Although if stricter inclusion criteria were

formulated, for example, the ATD group included euthyroid patients before pregnancy, the results of the study would be more targeted. If there are large-scale studies in the future, inclusion criteria can be further limited or subgroup analysis can be feasible.

The results of this paper are applicable for women with hyperthyroidism who seek pregnancy in the near future, if not, the results may not be applicable. Because with the extension of the time interval of treatment and pregnancy, the factors affecting pregnancy outcomes become more complex.

We did not identify other network meta-analysis evaluating the comparative safety of therapies for hyperthyroidism in a patient seeking future pregnancy to date. Our results would help clinicians and patients to make choices, and have positive significance for promoting eugenics. Our study has limitations, the primary one being the small number of included studies and enrolled patients, perhaps affecting the stability of our results. Second, our study included cohort studies increasing the risk of inherent bias. Third, network meta-analysis combines direct comparison and indirect comparison of evidence, and the results need careful interpretation. Fourth, because of the limited data, our study didn't explore the fetal outcome such as cesarean section, macrosomia, fetal distress, fetal death in utero, asphyxia, respiratory distress syndrome, endotracheal intubation, transfer to neonatal intensive care unit (NICU) and death. Fifth, the literature included in the study had short follow-up time about the birth defect, which might underrate the results. Finally, two literatures were not included in this network meta-analysis because the authors were not contacted up to date, which may have an impact on the final results.

Future research direction for therapies for hyperthyroidism in a women seeking near future pregnancy is to include more samples to conduct head-to-head randomized controlled trials or prospective cohort studies, establish inclusion criteria of various pre-pregnancy conditions or further subgroup analysis, and develop more acceptable, safer, and more manageable treatments that allow for the remission of both thyroid function and autoimmune abnormalities.

Figure 1. Study selection process

Table 1. characteristics of the included studies

Study name	Country	Diagnosis	Treatment setting	Treatment details	Sample size	Mean age (year)
Hawken 2016	France	GD	ATD vs surgery	ATD : Unclear Surgery:TT/ST (12/17)	49/29	29
Zhang 2016	China	GD	RAI Vs ATD	RAI : 1 /2 /3times (125/3/2) ATD : Unclear	130/127	29
Elston 2014	New Zealand	GD	surgery vs RAI	surgery: TT/ST (10/2) RAI : Unclear	12/17	28/31
Zhiwen Wu2018	China	hyperthyroidism	surgery vs ATD	surgery : ST ATD : PTU	58/58	26.2±3.4/26.8±3.5

Study name	Mean interval time between treatment and pregnancy	Medication between pregnancy	Thyroid function between pregnancy	Outcomes
Hawken 2016	ATD: Unclear Surgery: 3 (0-9) years	ATD : T1 : CMZ/PTU/stop (9/15/25) surgery : Unclear	ATD : Unclear Surgery: TSH > 2.5 (23) TSH < 2.5 (6)	abortion+premature delivery+ IUGR+ birth defect
Zhang 2016	At least 6 months	RAI: PTU/L-T4/no (43/69/18) ATD: PTU 或 L-T4/stop (106/21)	stable	abortion+premature delivery+ IUGR+ birth defect

Elston 2014	surgery: 19.6 (3-113.1) months	Surgery: Unclear	Euthyroid state : Surgery: (13/19)	abortion
	RAI: 32 (0.5-96.2) months	Surgery: ATD/L-T4/no (5/15/7)	RAI: (5/23)	
			TSH > 4 mU/L	
			Surgery: (9/19)	
			RAI: (12/24)	
Zhiwen WU2018	Unclear	Unclear	Unclear	abortion+premature delivery

TT: total thyroidectomy; ST: subtotal thyroidectomy; T1: first trimester of pregnancy

Table 2. Risk of assessment

The following table shows the risk of bias assessment for the individual studies.

study	selection				comparability	outcome			scores
	Representativeness of the exposed cohort	Selection of the non-exposed cohort	Ascertainment of exposure	Demonstration that outcome of interest was not present at start of study	Comparability of cohorts on the basis of the design or analysis	Assessment of outcome	Was follow-up long enough for outcomes to occur	Adequacy of follow up of cohort	
Hawken 2016	1	1	1	1	2	1	0	0	7
Zhang 2016	1	1	1	1	2	1	0	0	7
Elston 2014	1	1	1	1	2	1	1	0	8
Zhiwen Wu2018	1	1	1	1	1	1	1	0	7

The following table shows the risk of bias assessment for the individual domains.

Figure 2. network plot for all the outcomes

The size of the nodes corresponds to the number of participants assigned to each treatment. Treatments with direct comparisons are linked with a line; its thickness and the number on the line corresponds to the number of trials evaluating the comparison.

Table 3. heterogeneity parameter results in various outcomes

Outcomes	I^2
Abortion	0%
Premature delivery	0%
IUGR	10.4%
Birth defect	0%

Figure 3. Global inconsistency of abortion

$P=0.343>0.05$, suggesting the good consistency.

Table 4. Local inconsistency of abortion

Side	Direct		Indirect		Difference			tau
	coef	Std.Err.	Coef	Std.Err.	Coef	Std.Err.	P> z	
AB	-.2259175	.3649147	.9358467	1.168253	-1.161764	1.223919	0.343	1.68e-07
AC	.0823578	.7740259	-1.079407	.9480839	1.161765	1.22392	0.343	3.90e-07
BC	-.8534898	.8750431	.3082751	.8557329	-1.161765	1.22392	0.343	3.98e-07

$P=0.343>0.05$, suggesting the good consistency.

Table 5. comparison for pregnancy safety league table

Abortion rate	ATD	0.88 (0.45, 1.75)	0.68 (0.21, 2.21)
	1.13 (0.57,2.24)	RAI	0.77 (0.23, 2.56)
	1.47 (0.45,4.75)	1.30 (0.39,4.30)	Surgery
Preterm birth rate	ATD	0.98 (0.42, 2.33)	0.79 (0.39, 1.59)
	1.02 (0.43,2.41)	RAI	0.80 (0.26, 2.44)
	1.27 (0.63,2.55)	1.24 (0.41,3.78)	Surgery
IUGR rate	ATD	3.02 (0.60, 15.27)	0.83 (0.14, 4.86)
	0.33 (0.07,1.67)	RAI	0.28 (0.03, 3.02)
	1.20 (0.21,7.00)	3.63 (0.33,39.77)	Surgery
Birth defect rate	ATD	0.32 (0.03, 3.12)	0.23 (0.01, 4.52)
	3.12 (0.32,30.41)	RAI	0.70 (0.02, 30.34)
	4.44 (0.22,89.10)	1.42 (0.03,61.42)	Surgery

Figure 4. Ranking of comparative pregnancy safety of the interventons

A. Abortion

B. preterm birth

C. IUGR

D. Birth defect

Table 6. Ranking of comparative pregnancy safety of the interventions

A. Abortion

Treatment	SUCRA	PrBest	MeanRank
ATD	30.8	12.4	02.4
RAI	49.4	27.0	02.0
Surgery	69.8	60.7	01.6

B. premature delivery

Treatment	SUCRA	PrBest	MeanRank
ATD	36.7	11.8	02.3
RAI	43.0	30.5	02.1
Surgery	70.3	57.8	01.6

C. IUGR

Treatment	SUCRA	PrBest	MeanRank
ATD	66.3	37.9	01.7
RAI	12.0	05.4	02.8
Surgery	71.7	56.6	01.6

D. Birth defect

Treatment	SUCRA	PrBest	MeanRank
ATD	17.1	02.8	02.7
RAI	62.9	41.3	01.7
Surgery	70.0	55.9	01.6
