21 Abstract

22 **Background:** Quality is the most important factor of satisfaction. However, the existing
23 URRBMI index model lacks the decomposition of the connotation of perceived quality and
24 cannot provide a reference for quality improvement and satisfaction promotion.

25 **Objective:** This study aims to construct a Satisfaction Index Model for Chinese Urban and
26 Rural Residents Basic Medical Insurance (SIM-URRBMI) with accurate and detailed
27 measurement of perceived quality and give a feasible and scientific suggestion for URRBMI
28 or insurance for other countries in the world.

29 **Methods:** Based on the theoretical framework of The American Customer Satisfaction Index
30 (ACSI), the connotation of perceived quality was refined by literature review and expert
31 consultation to form a pool of alternative measurement variables. A three-stage randomized
32 stratified cluster sampling was adopted to select the main decision makers for pupils'
33 URRBMI in 8 primary schools from Changsha City. Both Classic Test Theory (CTT) and
34 Item Response Theory (IRT) were used for selection of the measurement variables. The
35 model's reliability and validity were tested using partial least square (PLS) related methods.

36 **Results:** A total of 1909 respondents who had insurance for their children were investigated
37 with the initial questionnaire. The revised SIM-URRBMI consists of 11 latent variables and
38 28 measurement variables with good reliability and validity. Among the three explanatory
39 variables of public satisfaction, perceived quality had the largest total effect (0.737). The
40 variable with greatest effect among the five first-order latent variables on perceived quality
41 was quality of the medical insurance policy (0.472).

42 **Conclusions:** The revised SIM-URRBMI consists of 11 latent variables and 28 measurement

43 variables with good reliability and validity. It provides accurate assessment of perceived
 44 quality, which will greatly help performance improvement. Perceived quality is crucial to
 45 public satisfaction, especially, the most important aspects are policies regarding medical
 46 insurance reimbursement (basic coverage scope, coinsurance, deductible).

47 **Keywords:** Satisfaction index model; Basic Medical Insurance for Urban and Rural Residents;
 48 PLS-SEM; reliability; validity

49 Introduction

50 According to the 2015 World Health Organization (WHO) report, 6% of people in low-
 51 and middle-income countries are forced into extreme poverty because of medical
 52 expenditures. The Chinese government has been trying to establish a multilevel medical
 53 security system that is mainly based on the social basic medical insurance (BMI) schemes so
 54 as to protect the finances of individuals and households affected by illness and injury to some
 55 extent. In order to improve equity, sustainability, and efficiency, China has taken an initial
 56 step to integrate new cooperative medical scheme (NCMS) and urban resident-based basic
 57 medical insurance (URBMI) into the urban and rural residents' basic medical insurance
 58 scheme (URRBMI) [1-2].

59 Voluntary enrollment is a principle of URRBMI in China [3]. The enrollee's satisfaction
 60 and loyalty are crucial for the scheme's effective implementation and sustained development.
 61 Moreover, analyzing the enrollee's satisfaction with their health insurance and its influencing
 62 factors can help to shed light on current and future policy decision making [0, 4-4]. ACSI is
 63 one of the most widely used and representative quantitative measurement scales that shows
 64 the cause-and-effect relationship linking the casual variables of customer satisfaction to their
 65 consequent effect variable (customer loyalty) [6]. The model construction theory of ACSI
 66 provides an important reference for assessing the attitude and major improvement direction of
 67 the URRBMI from the perspective of insured participants. Using the ACSI as a basis and
 68 considering the Chinese social and cultural backgrounds, Peng et al. constructed a satisfaction
 69 index model for URRBMI that demonstrated good reliability and validity for satisfaction
 70 measurement[7-8]. There has been sufficient literature supporting the notion that perceived

71 quality may be the most worthwhile topic in service area satisfaction research, and
 72 satisfaction is mainly determined by perceived quality [6, 9-10]. However, Peng's model only
 73 adopted a few indicators to assess perceived quality, such as the overall quality assessment
 74 question, "how much help does the URRBMI bring to your child?". The lack of
 75 comprehensive and detailed aspects of URRBMI quality measurement greatly limit its further
 76 use in health reform [7-8].

77 In addition, since significant variation in economic and cultural backgrounds,
 78 accessibility of health services, and reimbursement policies existed between rural and urban
 79 residents before the URRBMI integration, it is necessary to consider the modeling
 80 heterogeneity from a theoretical and practical perspective to learn about the differences
 81 between groups of the insured (rural VS urban) [11].

82 The aims of this study are to revise and validate the SIM-URRBMI and identify the main
 83 quality aspects needed to be improved in order to provide a valid, reliable, and practical
 84 satisfaction measurement tool for URRBMI. In addition, using heterogeneity analysis, we aim
 85 to explore the differences in satisfaction mechanism between rural and urban participants.

Materials and Methods

Participants and Sampling

This study was conducted in Changsha, the capital city of the Chinese Province of Hunan, which completed the integration of NCMS and URBMI in 2011. A three-stage randomized stratified cluster sampling method was used to ensure a representative sample. The first stage was to randomly select two districts/counties from the nine districts/counties of Changsha City. The second stage was to randomly select two primary schools for each selected district/county. Finally, for each selected school, six classes (one class from each grade) were randomly selected, and questionnaires were sent home; the main family decision maker responsible for the pupils' URRBMI was instructed to fill out the questionnaires. The inclusion criteria were: a) had insurance for their children in 2017-2018; b) were inhabitants of a city or village in Changsha; c) were the main decision maker for pupils' URRBMI in their family. Both the students in the selected classes and the main family decision makers responsible for the pupils' URRBMI were subjects of investigation.

This study used a graded response model (GRM) to identify the measurement variables. In order to make the estimated parameters more accurate, a sample size of at least 500 cases is suitable. The selected samples of measurement variables included in this paper are 574 cases, which meet the requirements[13]. The sample size for model evaluation was calculated by the following formula, $n \geq 50r^2 - 450r + 1100$ (r is the ratio of measurement variables to latent variables), which was based on the structural equation model research conducted by Westland et al. A minimum sample size of 216 was estimated. However, considering the need for subgroup analysis, a sample size of 1335 was obtained for model evaluation, which met the

108 estimated requirements [13-14].

109 **Ethical approval**

110 The study protocol was reviewed and approved by the Medical Ethics Committee at Xiang
111 -ya School of Public Health, Central South University. Written informed consent was obtai
112 ned for each participant who was the medical insurance decision maker of the family.

113 **Model construction**

114 **Phase 1**

115 The programmed decision process, a method to simultaneously develop a scale by
116 nominal group (including pupils and their family members, local medical insurance
117 management and service officers, experts of social medicine, health management, primary
118 health care, health statistics, and epidemiology et al.) and focus group (1 project leader, 1
119 professor of epidemiology and health statistics, 1 health insurance administration, and 4
120 graduate students), was used to construct the model. With reference to the literature, we
121 refined the "perceived quality" variable to five first-order latent variables, namely, overall
122 quality, information quality, service quality, policy quality, and institution quality. The draft
123 model consisted of 11 latent variables, including public expectations (PE), perceived quality
124 (PQ) (which was a second-order latent variable and consisted of the five first-order latent
125 variables), perceived value (PV), public satisfaction (PS), public complaints (PC), and public
126 trust (PT). Public expectation, perceived quality, and perceived value were the explanatory
127 variables of public satisfaction, while public complaints and public trust were the outcome
128 variables of public satisfaction. Consistent with Peng's research, we used the term "public" as
129 an alternative of the term "customer" and changed "customer loyalty" to "public trust". Then,
130 an initial draft variable pool (29 variables) was generated (see Table 1). Since the path of

131 public complaints on public trust was not significant according to Peng's research, this path

132 was not set in the initial draft SIM-URRBMI.

133

134

135

136 **Table 1** The latent and measurement variables of the initial SIM_URRBMI

Latent variable	First-order latent variable	Measurement variables
Public Expectation		Overall expectations (PE1)
		Expectations of URRBMI to ensure basic medical needs (PE2)
		Expectations of URRBMI to ensure personalization medical needs (PE3)
Perceived Quality	Overall quality	Overall evaluation of quality (PQ1)
	Information quality	Availability of related information (PQ2)
		The convenience of obtaining relevant information (PQ3)
	Service quality	Service attitude of staff (PQ4)
		Clarity of staff's interpretation of relevant policies (PQ5)
		Degree to meet the basic health insurance needs (PQ6)
	Policy quality	Degree to meet the personalized health insurance needs (PQ7)
		Satisfaction with the payment level (PQ8)
		Satisfaction with the scope of reimbursement (PQ9)
		Satisfaction with the reimbursement proportion (PQ10)
		Satisfaction with the deductible level (PQ11)
	Quality of institutions	Satisfaction with the capitation (PQ12)
		Service quality of community or village committees for enrollment (PQ13)
		Quality of payment bank or online payment platform (PQ14)
		Service quality of authorized medical institution (PQ15)
Perceived Value		Service quality of reimbursement in medical institution (PQ16)
		Service quality of authorized pharmacy (PQ17)
Public Satisfaction		Quality according to the payment (PV1)
		Payment according to the quality (PV2)
		Overall satisfaction (PS1)
		Service satisfaction to meets expectations (PS2)

	Distance close to the ideal medical insurance (PS3)
Public Complaint	Complained informally about URRBMI (PC1)
	Complained formally about URRBMI (PC2)
Public Trust	Willingness to positively evaluate (PT1)
	Willingness to recommend (PT2)

137

138 Based on expert consultation and literature review, the following path hypotheses were
139 established in the study (Fig 1):

140 **Fig1 The initial draft of SIM_URRBMI**

141 Hypothesis 1: Public expectation has a direct positive impact on perceived quality,
142 perceived value, and public satisfaction;

143 Hypothesis 2: Perceived quality has a direct positive impact on perceived value and
144 public satisfaction;

145 Hypothesis 3: Perceived value has a direct positive impact on public satisfaction;

146 Hypothesis 4: Public satisfaction has a direct positive impact on public trust;

147 Hypothesis 5: Public satisfaction has a direct negative impact on public complaints.

148 **Phase 2**

149 Classic Test Theory (CTT) combined with Item Response Theory (IRT) was applied for
150 the measurement variable selection. If a measurement variable reached 3 or more deletion
151 criteria, it was considered for deletion. CTT is based on the true score model (true score plus
152 error), and its selection methods and criteria are shown in Table 2. The basic idea of IRT is to
153 use a mathematical function to characterize the relationship between the test response; in this
154 study, θ refers to subject satisfaction with URRBMI. For the graded response model (GRM)
155 in this study, the discrimination parameter (a), Threshold Parameter (b), and Item Information

Function (*IIF*) were used to evaluate the quality of measurement variables. In addition, the Test Information Function (*TIF*) is a linear cumulative measurement of each item *IIF*; that is, the test information function on the θ value is equal to the sum of its *IIFs*. It is generally considered that the quality of the model is good when the total of the information function is greater than 25, while the quality is considered poor when the information function is less than 16[15-16]. Since the initial draft of the SIM-URRBMI contains a total of 29 measurement variables, the average information function amount of each measurement variable required ($\bar{I}$) ≥ 0.55 ($16 / 29$). The deletion criteria based on IRT are as follows: (1) a is less than 0.3; (2) b is out of range of (-4,4); and (3) $\bar{I}$ is less than 0.55.

165

Table 2 Item selection methods and criteria based on CTT

Methods	Criteria	Main test aspects
Floor effect	If 20% or more individuals choose the lowest score value, then delete it.	Sensitivity
Ceiling effect	If 20% or more individuals choose the highest score value, then delete it.	Sensitivity
<i>t</i> -test	The measurement variables with no statistically significant difference were deleted ($\alpha=0.05$) between 27% of the individual groups with the highest and lowest satisfaction scores.	Sensitivity or discrimination
Cronbach's α coefficient	If there is a large increase in the Cronbach's α of the dimension after the removal of an observed variable, then delete it.	Internal consistency
Correlation analysis 1	If the Pearson correlation coefficient of each measurement variable score and its corresponding dimension score is less than 0.6, then delete it.	Sensitivity or representation
Correlation analysis 2	If the Pearson correlation coefficient of each observed variable score and the initial model total score is less than 0.4, then delete it.	Representation
Stepwise regression	Using the total score of each latent variable as the dependent variable, the stepwise regression analysis is performed with candidate measurement variables as independent variables ($slr = 0.05$, $sls = 0.10$). The measurement variable excluded from the model will be deleted.	Importance
Factor analysis	Measurement variables with a factor load less than 0.4 will be deleted.	Independence

166

167 **Model validation**

168 The model validation includes two parts. The major reliability and validity tests were
 169 used to evaluate the measurement model. The value of Cronbach's α coefficient and the
 170 composite reliability coefficient were greater than 0.7. It is considered to indicate good
 171 reliability, and higher values indicate greater homogeneity. Outer loading (≥ 0.708) and
 172 Average Variance Extraction (AVE) (≥ 0.5) were used to assess the convergence validity, while
 173 the Cross Loading and Fornell-Larcker criteria were used to assess discriminant validity.

174 Good discriminant validity means that the outer loading of a measurement variable on its
175 corresponding latent variable is greater than its cross loadings on other latent variables, or the
176 square root of the *AVE* of each latent variable is greater than its linear correlation coefficients
177 with any other latent variables. Path analysis of the latent variables and model prediction were
178 used to evaluate the structural model [11]. The relationship between latent variables was
179 evaluated by estimating direct effect, indirect effect, and total effect. The model prediction
180 assessment indicators were the adjusted coefficient of determination (R_{adj}^2) (In general, R_{adj}^2
181 values of 0.25, 0.50, and 0.75 for target constructs are considered weak, medium, and
182 substantial, respectively.), the effect size (f^2) (Results of 0.02, 0.15, and 0.35 are interpreted
183 as small, medium, and large f^2 effect sizes, respectively.), and the predictive relevance (Q^2)
184 (The path model has predictive relevance for a selected endogenous construct if the Q^2 value
185 is above zero).

186 **Statistical analysis**

187 Second-order Partial Least Squares Structural Equation Model (PLS-SEM) was used to
188 test the model's reliability and validity, and PLS-SEM Multigroup Analysis (PLS-MGA) was
189 used to explore the heterogeneity between rural and urban participants. A two-tailed $P \leq 0.05$
190 was considered statistically significant. To be consistent with the international customer
191 satisfaction index, a one hundred percentage point system was used to express the public
192 satisfaction index (*PSI*).

193 The descriptive statistics and CTT analyses were conducted using SPSS 18.0. IRT
194 analysis was performed using Mplus version 7.0. PLS-SEM and PLS-MGA analyses were
195 conducted with SmartPLS 3.0.

196 Results

197 Samples

198 A total of 1909 participants who had insurance for their children were included in the
199 primary data analysis. Table 3 shows the sociodemographic information of pupils and main
200 decision makers for the model construction group and model validation group separately. For
201 pupils, the mean age was 9.26±1.75, and the frequency of male (945, 49.89%) and female
202 students (949, 50.11%) were similar. For the main decision makers, the mean age was
203 37.13±5.90 years; most of decision makers were parents of pupils (1845, 96.95%), especially
204 mothers (1196, 62.85%). Table 3 also indicates that there were no significant differences
205 between the two groups for both pupils and main decision makers , suggesting that the two
206 groups were homogenous. The measurement scores and comparative analysis between the
207 two groups are shown in S1 Table .

PQ_service	0.845	0.928
PQ_policy	0.933	0.946
PQ_institution	0.926	0.944

234 **Validity**

235 The results of the convergent and discriminant validity of the revised SIM-URRBMI are
236 summarized in Tables 6 - 8. The *AVEs* of all latent variables were greater than 0.5, and the
237 outer factor loadings of all the measurement variables ranged from 0.726 to 1.000, except
238 that the second-order external factor loadings for the PQ1, PQ2, and PQ3 variables (0.692,
239 0.595 and 0.684, respectively) was slightly below the critical value of 0.7, showing good
240 convergent validity. All of the outer loadings of the measurement variables on their
241 corresponding latent variable were greater than their cross loadings on the other latent
242 variables. The square roots of the *AVEs* for each latent variable were greater than the linear
243 correlation of the latent variable with the other structures, except for the perceived quality
244 variable, which has a slightly higher correlation with perceived value and public
245 satisfaction (Table 8). The results indicate good discriminant validity. All but one of the paths
246 were statistically significant and positive; the effect of public satisfaction on the public
247 complaints was negative, which is in line with the model theory framework. Table 9 and S3
248 Table show the result of the direct effects and the collinearity assessment of the
249 SIM-URRBMI. Furthermore, the greatest effect of the five first-order latent variables on
250 perceived quality was medical insurance policy quality (0.472) followed by institution quality
251 (0.354) (see Table 9). All variance inflation factor (*VIF*) values are clearly below the threshold
252 of 5. Therefore, collinearity among the predictor constructs is not an issue in the structural
253 model. The two paths with the greatest direct effect were perceived quality on perceived value
254 (0.676) and public satisfaction on public trust (0.634). S4 Table indicates the indirect effects

255 of the revised SIM-URRBMI.

The total effect of the 14 paths of the SIM-URRBMI were statistically significant, showing that the model was constructed properly (see Table 10). The three strongest paths were (1) perceived quality on public satisfaction (with a total effect of 0.737, a direct effect of 0.421 and an indirect effect of 0.316); (2) perceived quality on perceived value (with a total effect of 0.676); and (3) public satisfaction on public trust (with a total effect of 0.634). The largest total effect of the five explanatory variables of public trust was calculated for public satisfaction (0.634), followed by perceived quality (0.467). Among the three explanatory variables of public satisfaction, the greatest total effect was from perceived quality (0.737).

^a indicates that only the direct path was set, ^b indicates that only the indirect path was set

The adjusted coefficients of determination (R_{adj}^2) of each endogenous latent variable ranged from 0.088 to 1.000. The R_{adj}^2 values were 0.783 and 0.400 for public satisfaction and public trust, respectively, indicating a strong and moderate prediction. The effect size (f^2)

279 ranged from 0.014 to 0.903; the f^2 values for perceived quality on predicted perceived value,
 280 the perceived value on predicted public satisfaction, and public satisfaction on predicted
 281 public trust were 0.903, 0.351 and 0.667, respectively; all were greater than 0.35 indicating a
 282 strong predictive effect. The predictive relevance (Q^2) of all endogenous latent variables was
 283 greater than 0, ranging from 0.105 to 0.585, showing a certain predictive relevance for all five
 284 endogenous latent variables (see Table 11).

286 **Model application**

287 The SIM-URRBMI satisfaction index scores were 57.29 and 58.17 for rural and urban
 288 participants, respectively. PLS-MGA showed that the total effect of public expectation on
 289 public satisfaction and public complaints was higher for citizens than for rural residents
 290 (0.627 vs 0.534, $P=0.037$; -0.166 vs -0.114, $P=0.042$). The total effect of perceived quality on
 291 public trust for citizens was lower than that of rural residents (0.429 vs 0.514, $P=0.023$) (see
 292 Table 12).

297

298 Discussion

299 China's medical reform has entered a critical period, there is an urgent need to understand
300 participants' satisfaction with BMI and to determine the main aspects that need improvement.
301 This work will provide important evidence for the performance improvement of the insurance
302 schemes and provide a critical reference for reform [4]. After more than 60 years of reform
303 and construction, China has finally established a basic medical insurance system that covers
304 the entire population for basic medicine. To meet participants' growing basic need for a better
305 life, it is necessary to continuously improve the quality of universal medical insurance from
306 the perspective of the insured [17].

307 Moreover, the quality of medical insurance determines the satisfaction of the insured to a
308 large extent. The original SIM-URRBMI developed by Peng et al has provide a standard
309 measurement of satisfaction, but could not provide detailed information for the diagnosis of
310 poor quality as there were few detailed quality items. This study constructed the perceived
311 quality variable as a second-order latent variable based on the literature review and expert
312 consultation. The second-order SEM can not only reduce the number of structural model
313 relationships but also make the model path more concise and easier to understand. Most
314 importantly, it can measure the quality perception of URRBMI participants more accurately.
315 This characteristic will greatly help identify the aspects of URRBMI that are in urgent need of
316 improvement [18]. The results of the predictive ability evaluation showed that the R^2_{adj} of
317 PS was 0.783, which is larger than the R^2 of PS in the original version of SIM-URRBMI
318 constructed by Peng et al. (0.63). From this point of view, it appears that the construction of
319 PQ as a second-order latent variable in this study increased the predictive power of public

320 satisfaction. This also verifies our hypothesis that the quality-refined model can measure PS
321 more accurately.

322 Additionally, this study also tested the path effect differences between rural and urban
323 participants; thus, it can not only reveal population heterogeneity in structural models but also
324 help identify the preferred path for quality and satisfaction improvement in a certain subgroup
325 population.

326 The measurement variables selection is a key step in model construction. CTT and IRT
327 complementary each other, combining both methods in measurement variable selection will
328 provide more stable and reliable choices and benefits for model construction. The result of
329 measurement variable selection revealed that the measurement variable PC2 (formal
330 complaint) had poor performance. It is consistent with Chinese cultural backgrounds that the
331 public seldom choose this method to express their dissatisfaction with public services.
332 Deletion of PC2 suggested that this study had a good rationale for its measurement variable
333 selection methods [19].

334 The Cronbach's α coefficients and composite reliability coefficients for all latent
335 variables were greater than 0.7, suggesting good internal consistency. except for the
336 perceived quality variable, which was slightly less than the linear correlation coefficient
337 between the perceived value and public satisfaction variables (One possible reason is that the
338 second-order external factor loadings for the PQ1-PQ3 variables were less than 0.7), all the
339 other results indicate that the model has good convergent validity and discriminant
340 validity. The total effect of perceived quality on public satisfaction is 0.737, which has the
341 largest total effect among all latent variables, indicating that PQ is the most important factor

affecting public satisfaction, which is consistent with the research conducted by Lang Xu and Fornell C in the medical insurance field and Johnson MD in other research fields [20-21]. First, from the results of the path coefficients between perceived quality and its first-order latent variables, it was seen that the quality of medical insurance policy had the greatest impact on PQ with a total effect of 0.472, suggesting that medical insurance policy had the greatest impact on public satisfaction. Second, PQ9 (basic coverage scope), PQ10 (coinsurance), PQ11 (deductible) and PQ12 (capitation) had larger second-order factor loadings on PQ. Moreover, PQ9-PQ12 had larger discrimination parameters (2.4-2.8) from the IRT *IIF* results. According to Juxiang Qin's point of view, the discrimination parameter reflects the sensitivity, which can distinguish the sensitivity of all the participants' responses to the question (that is, whether the project is a concern shared by everyone), and the *IIF* result reflects that the insured residents are more concerned about the policies related to reimbursement [22]. Therefore, reimbursement policy for URRBMI has the greatest impact on the satisfaction of the insured residents, suggesting that the improvement of quality, especially the medical insurance reimbursement policy quality, is crucial to improving satisfaction with URRBMI.

The SIM-URRBMI satisfaction index score of the main family decision makers for the pupils' BMI in Changsha was 57.59, which was lower than the satisfaction scores of the insured farmers on the NCMS in 2014 (66.33) and the US federal government satisfaction index scores (69.70) in 2017 [21, 23]. The satisfaction index score can also be used as a vertical comparison tool for the satisfaction research for URRBMI assessment. The satisfaction index scores were 57.29 and 58.17 in the rural and urban areas, respectively,

364 indicating that the urban residents had a slightly higher satisfaction level of URRBMI in
 365 Changsha, which is consistent with the research conducted by Fan Yan et al.[24]. The
 366 PLS-MGA result showed that, compared to the rural residents, urban participants had a higher
 367 total effect of PE on both PS and PC, while having a lower total effect of PQ on PT. PE is a
 368 kind of expectation for future medical insurance policies based on past consumption
 369 experiences. The urban residents had better policy welfare than the rural residents before the
 370 consolidation. Thus, urban residents had higher expectations for URRBMI, and whether the
 371 expectation is close or far from the actual situation, they may have, accordingly, had higher
 372 positive effects (satisfaction) or negative effects (complaints) than rural residents.

373 There are also some limitations of this research. First, the sample population was the
 374 main family decision makers for pupils' URRBMI and did not involve the other URRBMI
 375 participants in the family (such as college students). The conclusion is limited to the entire
 376 insured population. It is hoped that different insured populations can be included in future
 377 stages to expand the applicability of the model. Second, this study is a cross-sectional study
 378 that did not collect longitudinal data and, thus, could not estimate trends in URRBMI
 379 satisfaction in the sample area.

380 **Conclusions**

381   The final version of the SIM-URRBMI consists of 28 measurement variables and 11
382   latent variables. It is a reliable and valid satisfaction measurement tool with good prediction
383   ability for public satisfaction and public trust. In addition, the model provides accurate
384   assessment for perceived quality of URRBMI, which will greatly help for performance
385   improvement.

386 **Acknowledgements**

387   The authors would like to thank all the participants, teachers, and leaders in the selected
388   8 primary schools, Liuyang City Center For Disease Control and Prevention and Tianxin
389   District Education Bureau.
