Abstract

Roughly six months into the COVID-19 pandemic, many countries have managed to contain the spread of the virus by means of strict containment measures including quarantine, tracing and isolation of patients as well strong restrictions on population mobility. Here we propose an extended SEIR model to explore the dynamics of containment and then explore scenarios for the local extinction of the disease. We present both the deterministic and stochastic version of the model and derive the $\mathcal{R}_0$ and the probability of local extinction after relaxation (elimination of transmission) of containment, $\mathbb{P}_0$. We show that local extinctions are possible without further interventions, with reasonable probability, as long as the number of active cases is driven to single digits and strict control of case importation is maintained. The maintenance of defensive behaviors, such as using masks and avoiding agglomerations are also important factors. We also explore the importance of population immunity even when above the herd immunity threshold.

1. Introduction

The COVID-19 pandemic is among the top three biggest in the last on hundred years, reaching levels only previously seen in Influenza pandemics[1]. At the time of writing, more than 8 million confirmed cases have been reported globally, with more than 500 thousand deaths [2]. Most affected countries still observe transmission, even if number of new cases show signs of reduction. Even with few cases, if cities (or countries) decide to lift quarantine measures, transmission may increase again due to the presence of sizeable portion of susceptible individuals suddenly at greater risk of infection.

The initial containment response varied considerably across countries, with some countries displaying more success than others in avoiding infections and subsequent deaths[3, 4, 5]. The economic impact of the containment efforts in the form of quarantines, lock-downs, suspension of international travelling and other drastic measures, has been remarkable [6]. This economic strain has forced many countries towards an early suspension of many of the most severe containment measures such as quarantines and mobility restrictions [7]. Naturally, the re-normalization of social interaction brings with it may concerns about the potential for a second wave of transmissions, which could potentially grow out of control [8].

Thus, an important question that emerges after a period of isolation is: *What's the probability that local infections will be eliminated once the isolation is lifted?* Evaluating scenarios for incidence evolution after these initial containment efforts requires models which accommodate both biological and population-level dynamics. In particular, models that can represent properly the immunological aspects of COVID-19 progression as well as the impact of containment mechanisms, such as quarantine and social distancing.

Many models have been proposed recently to deal with the temporal evolution of the epidemic[9, 10, 11], but one key aspect that must be considered is the contribution of stochastic fluctuations to the interruption of local transmission after the number of active cases is brought close to zero. Kucharsky et al. (2020, [12]), used an stochastic transmission model to estimate the daily reproduction number, $\mathcal{R}_t$, which is often used to predict disease extinction ($\mathcal{R}_t < 1$), but empirical estimates of basic reproduction numbers are very sensitive to noise in the testing rates as well as to changes in case definition. Moreover, in real populations, $\mathcal{R}_t$ can move back above one quite

36 easily in response to changes in the population protective behavior.

37 In this paper, we approach the issue of local disease extinction by cal-
 38 culating the probability of extinction of the disease as a stochastic epidemic
 39 process. In the context of epidemics, the correct epidemiological terminology
 40 for the stochastic extinction is the local “elimination of infections”. In this
 41 paper, however, we shall continue to use the term extinction throughout,
 42 as it is shorter and more in line with the literature on stochastic processes.
 43 The probability of extinction is greater when the number of infected is low,
 44 so we calculate this probability assuming post-containment scenarios where
 45 cases have been dropped to very low numbers. We start by presenting the
 46 deterministic version of the model and derive its basic reproduction number.
 47 Then we derive an stochastic version of the same model and use it to calcu-
 48 late an analytical expression for the extinction probability. We conclude by
 49 looking at scenarios of local extinction and discussing how it applies to real
 50 scenarios, including also the impact of the fraction of the population already
 51 immunized upon the lifting of containment.

52 2. Methods

53 2.1. The SEIAHR model

54 First, we describe the (deterministic) model used to represent COVID-
 55 19 dynamics. The Susceptible-Exposed-Infectious-Removed (SEIR) model is
 56 a classic model for diseases for which it is important to take into account
 57 an incubation period, and variants of it have been employed in numerous
 58 COVID-19 modelling studies [13, 14]. Here, we propose a variation of this
 59 model with added asymptomatic, hospitalized compartments and a quaran-
 60 tine mechanism (fig. 1). There are no explicit compartments for Quarantined and
 61 dead individuals as they are pure sink states that do not influence the main
 62 dynamics.

Figure 1: Block diagram of the SEIAHR model. compartments Q and $death$ are included for illustrative purposes only.

The model is represented as system of ordinary differential equations:

$$\frac{dS}{dt} = -\lambda[(1 - \chi)S], \quad (1a)$$

$$\frac{dE}{dt} = \lambda[(1 - \chi)S] - \alpha E, \quad (1b)$$

$$\frac{dI}{dt} = (1 - p)\alpha E - \delta I - \phi I, \quad (1c)$$

$$\frac{dA}{dt} = p\alpha E - \gamma A, \quad (1d)$$

$$\frac{dH}{dt} = \phi I - (\rho + \mu)H, \quad (1e)$$

$$\frac{dR}{dt} = \delta I + \rho H + \gamma A, \quad (1f)$$

with $\lambda = \beta(I + A)$ as the force of infection. State variables S, E, I, A, R, H represent the fraction of the population in each of the compartments, thus $S(t) + E(t) + I(t) + A(t) + H(t) + R(t) = 1$ at any time t . Quarantine enters the model through the parameter χ which can be taken as a constant or as a function of time, $\chi(t)$, that represents the modulation of the isolation policies. Quarantine works by blocking a fraction χ of the susceptibles from being

69 exposed, i.e., taking part on disease transmission. Time-varying quarantine
70 is achieved through multiplying χ by activation (eq. 2) and deactivation (eq.
71 3) functions:

$$A_s(t) = \frac{1 + \tanh(t - s)}{2}, \quad (2)$$

72 and

$$D_e(t) = \frac{1 - \tanh(t - e)}{2}, \quad (3)$$

73 where s and e are the start and end of the isolation period ($e > s$), respec-
74 tively. A finite period $\tau = e - s$ of quarantine can be defined by the combined
75 effect of both functions:

$$\chi(t) = \chi A_s(t) D_e(t). \quad (4)$$

76 Figure 2 illustrates the activation and deactivation of quarantine.

77

Figure 2: $\chi(t)$ upon activation and deactivation of quarantine for $\chi = 0.3$. Panel on the left shows each function separately ($\chi A_1(t)$ and $\chi D_1(t)$) set to $t = 1$. The right panel shows a combination with activation on $t = 1$ and deactivation on $t = 6$ ($\chi(t) = \chi A_1(t) D_6(t)$).

79 2.2. Basic Reproduction Number

80 The basic reproduction number for the SEIAHR model can be derived using
81 the next generation matrix method[15], which we show in Appendix A. The
82 expression for $\mathcal{R}_0$ is

$$\mathcal{R}_0 = \frac{\beta(1 - \chi)(p(\phi + \delta) + (1 - p)\gamma)}{\gamma(\delta + \phi)}. \quad (5)$$

Table 1: State transitions and rates for the stochastic SEIAHR model. In the state transition column, only the changing state variables are indicated.

Description	State transition	rate
Infection	$(S, E) \rightarrow (S - 1, E + 1)$	$\lambda(1 - \chi)S$
Exposed to I	$(E, I) \rightarrow (E - 1, I + 1)$	$(1 - p)\alpha E$
Exposed to A	$(E, A) \rightarrow (E - 1, A + 1)$	$p\alpha E$
Hospitalization	$(I, H) \rightarrow (I - 1, H + 1)$	ϕI
Recovery of I	$(I, R) \rightarrow (I - 1, R + 1)$	δI
Recovery of A	$(A, R) \rightarrow (A - 1, R + 1)$	γA
Recovery of H	$(H, R) \rightarrow (H - 1, R + 1)$	ρH
Death of H	$H \rightarrow H - 1$	μH

83 From equation (5) we can obtain $\mathcal{R}_t = \mathcal{R}_0 S(t)$ and another reproduction
84 number, denoted by $\mathcal{R}_c$, which we shall call *control reproduction number*, as
85 it represents the average number of secondary cases infected by primary cases
86 under some control scenario – i.e. whenever $\chi > 0$.

87 2.3. Probability of extinction

88 The question of the local extinction the disease can be more realistically
89 addressed with a stochastic version of the SEIAHR model, where the com-
90 bination of a discrete state and stochastic state transitions allow for actual
91 extinctions to occur.

92 The transition rates from the ODE model (Eqs 1) listed on table 1, can be
93 used to build a continuous-time markov chain model where time is continuous
94 but the state is discrete, allowing for a more realistic description of population
95 changes over time.

This model is a multivariate stochastic process $\{S(t), E(t), I(t), A(t), H(t)\}$ where $R(t) = N - (S(t) + E(t) + I(t) + A(t) + H(t))$. We will leave the equation of R out, because it is decoupled from the rest of the system. A joint probability function is associated with the set of random state variables, $\{S(t), E(t), I(t), A(t), H(t)\}$,

$$P_{s,e,i,a,h}(t) = \Pr(S(t) = s, E(t) = e, I(t) = i, A(t) = a, H(t) = h),$$

which leads to the Kolmogorov forward equation

$$\begin{aligned} \frac{dP_{s,e,i,a,h}}{dt} = & P_{s+1,e-1,i,a,h}\lambda(1-\chi)(s+1) + P_{s,e+1,i-1,a,h}(1-p)\alpha(e+1) \\ & + P_{s,e+1,i,a-1,h}p\alpha(e+1) + P_{s,e,i+1,a,h-1}\phi(i+1) + P_{s,e,i+1,a,h}\delta(i+1) \\ & + P_{s,e,i,a+1,h}\gamma(a+1) + P_{s,e,i,a,h+1}\rho(h+1) + P_{s,e,i,a,h+1}\mu(h+1). \end{aligned} \quad (6)$$

As a continuous-time branching process, the extinction threshold for the stochastic model is closely related to the corresponding one in the deterministic model but depends on the initial number of infectious individuals[16]. Based of the properties of this kind of stochastic processes, Whittle (1955) calculated the probability of extinction for the stochastic SIR model to be $\mathbb{P}_0 = \left(\frac{1}{\mathcal{R}_0}\right)^i$, where i is the initial number of infectious individuals[17]. We can apply the same technique described for the stochastic SEIR model by Allen and Lahodny [16] to derive the probability of extinction for the SEIAHR model. The analysis presented in Allen and Lahodny [16] assume proximity to the DFE with a large enough number of susceptibles and a small number of infectious individuals. Assuming a value for $\mathcal{R}_0$ from other epidemics or estimated from initial exponential growth. For a realistic application to the COVID-19 epidemic at the moment t of the relaxation of population lockdown, we need to acknowledge that $S(t) < N$, whilst not knowing what the exact value of S at time t and thus the effective reproduction number at the time. Nevertheless, we know from equation (5) that $\mathcal{R}_t$ is a function of $S(t)$. Therefore, we calculate $\mathbb{P}_0$ for various values of $\mathcal{R}_t$.

Analytical expression for $\mathbb{P}_0$. The probability of extinction, $\mathbb{P}_0$, can be computed analytically following the derivation of probability-generating functions for the system of equations in (6), the details of which are given in Appendix B. The probability of extinction is computed from the fixed points of the PGFs, q_1 , q_2 and q_3 , which lie in $(0, 1)^3$. With the fixed points in hand, we arrive at

$$\mathbb{P}_0 = \prod_{i=1}^3 q_i^{k_i}, \quad (7)$$

where k_i are the initial states $k_1 = E(0)$, $k_2 = I(0)$ and $k_3 = A(0)$. Here we denote the moment of relaxation of containment as $t = 0$.

123 *Numerical approximation to $\mathbb{P}_0$.* The expression in (7), while very useful, is
 124 derived from the assumption that the initial state is small compared to the
 125 size of the population and that $S(0) \approx N$. Due to the possible deviations
 126 from the theoretical value of $\mathbb{P}_0$ when $S(0) < N$, In the results, we always
 127 present estimates of $\mathbb{P}_0$, obtained by simulation as well.
 128 We can approximate $\mathbb{P}_0$ for a given $\mathcal{R}_0$ and an initial number of infected in-
 129 dividuals ($E + I + A$). This can be accomplished by running a large number
 130 of simulations of the stochastic model and computing the fraction of simu-
 131 lations in which the virus is driven out of the population ($E + I + A = 0$)
 132 without first causing an outbreak. To facilitate setting up the simulation to
 133 specific $\mathcal{R}_0$, we can rewrite the force of infection by replacing β as a function
 134 of $\mathcal{R}_0$ (eq. A.8):

$$\beta = \frac{\gamma (\delta + \phi) \mathcal{R}_0}{(1 - \chi) [p\phi + p(\delta - \gamma) + \gamma]}. \quad (8)$$

135 2.4. Effect of Increasing Seroprevalence

136 After a first wave of infections a fraction of the population will become im-
 137 munized against SARS-COV-2. This will have a protective effect on the
 138 population even if $S(t)$ is still above the so-called “herd immunity” threshold
 139 of $1/\mathcal{R}_0$. The resulting adjusted $\mathbb{P}_0$ for different levels of population immu-
 140 nization can be determined through simulation of the stochastic SEIAHR
 141 model (eq. 6).

142 3. Results

143 Figure 3 shows how imposing strong containment measures can reverse the
 144 growth of the number of cases. But a second wave starts immediately after
 145 the restrictions are relaxed. Figure 4 shows that in three out of ten post-
 146 containment simulations, the containment resulted in the extinction of the
 147 disease, with the other resulting on a second wave.

148 Depending on the value of $\mathcal{R}_t$ at the moment the quarantine is lifted and the
 149 number of remaining active cases, the probability of extinction can favor the
 150 stochastic extinction of the disease (Fig 5).

151 Tables 2 and 3 contain the values of $\mathbb{P}_0$ for different scenarios of number of
 152 infectious, with high and low $\mathcal{R}_0$ respectively.

153 We also estimated the $\mathbb{P}_0$ adjusted for different fractions of immune individ-
 154 uals (R) in population from 10000 simulations of the stochastic model. The
 155 results are presented in table 5.

Figure 3: Effect of containment, $\chi = .99$ for 55 days starting on the 50th day of the epidemic. Simulation parameters were $\phi = 0.01$, $\mathcal{R}_0 = 1.7$, $\rho = 0.21$, $\delta = 0.04$, $\alpha = 0.34$, $\mu = 0.02$, $p = 0.76$, $s = 50$, $e = 105$.

Table 2: Probabilities of extinction for $\mathcal{R}_t = 2.5$. Approximate $\mathbb{P}_0$ was calculated from a set of 10000 runs of the stochastic SEIAHR model with different number of initial infectious individuals(I_0).

I_0	E_0	A_0	Approx. $\mathbb{P}_0$	SEIAHR $\mathbb{P}_0$	SIR $\mathbb{P}_0$

5	0	0	0.63	0.68	0.62

Table 5: Adjusted $\mathbb{P}_0$ for different levels seroconversion($R(0)$) of the population. Results are the fraction of stochastic extinctions in 10000 simulations, with $\mathcal{R}_0 = 1.1$.

I_0	$R(0)$	$\mathbb{P}_0$
10	0	0.35
10	0.1	0.60
10	0.2	0.82
10	0.3	0.93
15	0.3	0.91
20	0.3	0.88
45	0.3	0.78

Table 6: Expected time to elimination of infections, in days, counting from the end of containment. Time is expressed as mean and 95% interval. Values were estimated from a 10000 runs of the stochastic SEIAHR model and rounded to the nearest integer number of days.

Immune fraction	I_0	Time to extinction in days
0	10	149 [38, 325]
0	5	105 [17, 313]
0	1	36 [1, 185]
0.2	10	145 [32, 333]
0.2	5	99 [15, 313]
0.2	1	36 [1, 201]
0.4	10	147 [34, 301]
0.4	5	103 [15, 308]
0.4	1	37 [1, 216]

Table 6 shows the expected time in days until extinction under different levels of population immunity and post-containment number of infected.

4. Discussion

Most countries who managed to control the first wave of COVID-19 did it by means of imposed restrictions on human-to-human contact. Be it through quarantine, tracing and isolation, use of masks or a combination of social distancing tactics, they managed to minimize contacts and thus transmission. Here we have introduced a transmission model (SEIAHR) in both deterministic and stochastic formulation, which includes the isolation of susceptibles as a means of reducing transmission as well as different levels of infectious individuals. From these models (deterministic and stochastic versions) it is possible to explore the consequences of social distancing as well as to calculate the probability of a second wave upon the suspension of distancing behavior. Figure 3 shows how imposing strong social distancing can interrupt the transmission, bringing the prevalence to near zero. However, if steps are not taken to permanently change the way people interact in their daily routine, at work, school, public transport, etc. The reproduction number upon lifting of the restrictive regulations, will still be substantially higher than one and will drive a powerful second wave if the population is still far from herd immunity conditions.

176 In the deterministic version of SEIAHR, a second wave will always happen
 177 due to the asymptotic way that the number of infectious approach zero.
 178 Treating the epidemic process as the stochastic process that it actually is,
 179 we can see that the probability of local extinction post-reactivation is quite
 180 substantial (fig 5). In the stochastic SEIAHR, extinction events will happen
 181 with slightly lower probabilities than those of a SIR model justifying using
 182 more detailed model to study this problem. Figure 4 shows stochastic ex-
 183 tinction taking place in three out of ten runs, with $\mathcal{R}_t = 1.7$ and $I_0 = 2$. The
 184 Stochastic model allows us to compute the probabilities of eliminating local
 185 transmission under various scenarios, and can be a useful tool for planning
 186 when to lift restrictions to human mobility and interaction.
 187 Though the probabilities of elimination of local infections seem rather low
 188 on the basic scenarios described on tables 2, 3 and 4, these do not tell us the
 189 whole story. If one takes into account the immunity acquired by the popula-
 190 tion during the containment period, one can see from the results in table 5,
 191 that even if a location is still far from achieving herd immunity, any acquired
 192 immunity will greatly improve the chances local extinction substantially.
 193 Communities that managed to contain the disease and bring it to the brink
 194 of extinction with severe economic impact, need to know how likely they are
 195 in succeeding in their fight against the disease as they return to “normal”
 196 social and economic activities. Our results also reinforce the need to run
 197 seroprevalence surveys previous to the reopening so that the probability to
 198 eliminate local infections e properly adjusted for the context of each locality.
 199 Here we explored how to improve the chances for local transmission elimina-
 200 tion but it must be kept in mind that the $\mathcal{R}_t$ must be kept low (through the
 201 use of masks and social distancing) in the post-containment period to guar-
 202 antee elimination and even when properly executed the time to elimination
 203 can vary from weeks to months, as shown in table 6.

258 Appendix A. Derivation of the basic reproduction number

259 In order to use the next-generation method, we start by identifying all m
260 compartments containing infected individuals. In this case they are E , I
261 and A and $m = 3$. Let $\mathcal{F}$ be the vector of the rates of appearance of new
262 infections in the three infectious compartments:

$$\mathcal{F} = \begin{bmatrix} \lambda(1 - \chi)S \\ 0 \\ 0 \end{bmatrix}. \quad (\text{A.1})$$

263 Next, we let $\mathcal{V}_i(x)^-$ be rate infectious individuals leave compartment i , and
264 $\mathcal{V}_i(x)^+$ be the rate with which they enter compartment i :

$$\mathcal{V}^- = \begin{bmatrix} \alpha E \\ (\delta + \phi)I \\ \gamma A \end{bmatrix}, \quad (\text{A.2})$$

265 and

$$\mathcal{V}^+ = \begin{bmatrix} 0 \\ (1 - p)\alpha E \\ p\alpha E \end{bmatrix}. \quad (\text{A.3})$$

266 After defining these we can calculate $\mathcal{V}(x) = \mathcal{V}_i(x)^- - \mathcal{V}_i(x)^+$:

$$\mathcal{V} = \begin{bmatrix} \alpha E \\ (p - 1)\alpha E + (\delta + \phi)I \\ -p\alpha E + \gamma A \end{bmatrix}. \quad (\text{A.4})$$

267 Now, if we let $x = \{E, I, A\}$ and x_0 be the Disease-free equilibrium (DFE),
268 we can define

$$F = \left[\frac{\partial \mathcal{F}_i}{\partial x_j}(x_0) \right] = \begin{pmatrix} 0 & -S\beta(\chi - 1) & -S\beta(\chi - 1) \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad (\text{A.5})$$

269 and

$$V = \left[\frac{\partial \mathcal{V}_i}{\partial x_j}(x_0) \right] = \begin{pmatrix} \alpha & 0 & 0 \\ \alpha(p - 1) & (\delta + \phi) & 0 \\ -\alpha p & 0 & \gamma \end{pmatrix}. \quad (\text{A.6})$$

270 The next generation matrix is given by FV^{-1} :

$$\mathbb{K} = \begin{pmatrix} -\frac{(S\beta\chi - S\beta)p\phi + (S\beta\chi - S\beta)\gamma + ((S\beta\chi - S\beta)\delta - (S\beta\chi - S\beta)\gamma)p}{\delta\gamma + \gamma\phi} & -\frac{S\beta\chi - S\beta}{\delta + \phi} & -\frac{S\beta\chi - S\beta}{\gamma} \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad (\text{A.7})$$

271 The spectral radius of $\mathbb{K}$ at the DFE (when $S(0) \approx 1$), is the basic reproduc-
272 tion number of the model, $\mathcal{R}_0 = \rho(FV^{-1})$,

$$\mathcal{R}_0 = -\frac{(\beta\chi - \beta)p\phi + (\beta\chi - \beta)\gamma + ((\beta\chi - \beta)\delta - (\beta\chi - \beta)\gamma)p}{\delta\gamma + \gamma\phi}, \quad (\text{A.8})$$

273 which, after simplification, gives equation (5).

274 Appendix B. Probability generating functions

Following [16], we derive the probability-generating functions (PGF) for each infectious compartment. Starting with $I_i(0)$, the probability of an infected individual in state i producing offspring of type j given that $I_j(0)$ can be obtained from

$$f_i(z_1, \dots, z_k) = \sum_{j_k=0}^{\infty} \cdots \sum_{j_1=0}^{\infty} P_i(z_1, \dots, z_k) z_1^{j_1} \cdots z_k^{j_k}.$$

275 The desired probabilities can be obtained by differentiating the PGF with
276 respect to z_i and setting all $\mathbf{z}$ to 1. Notice f_i has a fixed point at $z_1 = \dots =$
277 $z_k = 1$.

278 Computing the relevant probabilities is straightforward by keeping track of
279 the possible transitions (given in Table 1) and considering that only one
280 transition may occur in a given time interval Δt . First, when $E(0) = 1$,
281 $I(0) = 0$ and $A(0) = 0$, we have

$$f_1(z_1, z_2, z_3) = (1 - p)z_2 + pz_3, \quad (\text{B.1})$$

282 and when $E(0) = 0$, $I(0) = 1$ and $A(0) = 0$ the PGF is

$$f_2(z_1, z_2, z_3) = \frac{\beta(1 - \chi)z_1z_2 + \delta + \phi}{\beta(1 - \chi) + \delta + \phi}. \quad (\text{B.2})$$

283 Finally, for the case $E(0) = 0$, $I(0) = 0$ and $A(0) = 1$:

$$f_2(z_1, z_2, z_3) = \frac{\beta(1-\chi)z_1z_3 + \gamma}{\beta(1-\chi) + \gamma}. \quad (\text{B.3})$$

284 From the PGFs, we can obtain a matrix $\mathbb{M}$ whose entries $m_{ji} = \frac{\partial f_i}{\partial u_i}|_{u=1}$ are
 285 the expected number of offspring in state j from an individual in state i .

286 Given the PGFs above, we arrive at

$$\mathbb{M} := \begin{bmatrix} 0 & 1-p & p \\ \frac{\beta(1-\chi)}{\beta(1-\chi)+\delta+\phi} & \frac{\beta(1-\chi)}{\beta(1-\chi)+\delta+\phi} & 0 \\ \frac{\beta(1-\chi)}{\beta(1-\chi)+\gamma} & 0 & \frac{\beta(1-\chi)}{\beta(1-\chi)+\gamma} \end{bmatrix}. \quad (\text{B.4})$$

To obtain the probability of extinction, $\mathbb{P}_0$, we need to find the fixed points of the PGFs, i.e. solutions to equations of the form $f_i(q_1, q_2, q_3) = q_i$, $q_i \in (0, 1)$. After some tedious algebra, we arrive at

$$q_1 = \frac{-\sigma + (1-\chi)\beta + (\phi + \delta) + \gamma}{2(1-\chi)\beta}, \quad (\text{B.5})$$

$$q_2 = \frac{(\phi + \delta)(\sigma - (1-\chi)\beta - (\phi + \delta) + \gamma)}{2(1-\chi)\beta(p-1)((\phi + \delta) - \gamma)}, \quad (\text{B.6})$$

$$q_3 = \frac{\gamma(\sigma - (1-\chi)\beta + (\phi + \delta) - \gamma)}{2(1-\chi)\beta p((\phi + \delta) - \gamma)}. \quad (\text{B.7})$$

287 with $\sigma = \sqrt{((1-\chi)\beta)^2 + 2(1-\chi)\beta(2p-1)((\phi + \delta) - \gamma) + ((\phi + \delta) - \gamma)^2}$.
