Abstract

Introduction : Despite limited scientific evidence, trigeminal nerve blocks are alternative therapies for refractory trigeminal neuralgia (RTN). The duration of analgesia far exceeds the length of the conduction block. This study evaluated the quality of life 15 days after performing this block to treat RTN.

Methods : This retrospective study included all patients who, after informed consent, received iterative trigeminal blocks to treat a RTN between 2014 and 2018 in a university hospital. Patients received 0.5% levobupivacaine in combination with clonidine and a corticosteroid (cortivazol or betamethasone according to their availability). Data were obtained from patients' medical data files and a telephone questionnaire for the SF-12 score. The main criteria of evaluation was the change in quality of life according to SF-12 performed at day 15.

Results : Twenty-one patients aged 62 ± 14 years were included. All patients exhibited RTN after many different clinical treatments according to ICHD-3 criteria. Seventy-one per cent of RTN occurred after trauma or surgery. Before receiving blocks, SF-12 physical (SF-12-PS) and mental (SF-12 MS) scores reached respectively 35 ± 14 and 29 ± 11 . A mean time of 4 ± 5 years elapsed between the occurrence of RTN and nerve blockade. At day 15, SF-12 PS increased by a 3 point mean value and SF-12 MS by 5 points. Approximately half of the patients (55%) were considered as non-responders with a cut-off value of less than 10% variation of their initial SF-12 score. When excluding these patients, SF-12 PS and SF-12 MS were increased by 17 and 9 points respectively. The mean duration of blocks lasted 15 ± 59 days and no severe adverse effects were observed. Patient satisfaction was correlated with increased SF-12 PS ($r^2 = 0.3$, $p = 0.01$) and with the length of analgesia ($r^2 = 0.51$, $p = 0.001$) but not to SF-12 MS variation ($p = 0.12$).

Conclusion : Trigeminal nerve blocks are temporarily effective on pain that may increase the quality of life in responder patients. The reason why some patients are unresponsive to this treatment and why durations of efficacy are so variable remain unsolved. However, in responders, trigeminal nerve blocks seem simple, harmless, not excessively cumbersome and without severe adverse effects.

Introduction

Chronic pain is a multidimensional illness with a severe negative impact on patient quality of life. Trigeminal neuralgia is a clinical entity involving many etiologies causing a neuropathic pain that is sometimes refractory to all medical treatments¹. Its incidence reaches 12/100,000 people/year and 1.8/100,000 people /year when neuralgia involves only one branch of the trigeminal nerve². Twenty-five percent of these neuralgias are refractory to carbamazépine³, and surgical advice is recommended as first line treatment. Alternative therapies such as peripheral trigeminal blocks may be proposed to patients despite limited scientific evidence^{4,5}. According to experts, improvement of functional status and quality of life must be the main criteria to evaluate the utility and effect of loco-regional anesthesia to treat chronic pain⁵. Trigeminal block efficacy on chronic pain is controversial but when effective, its prolonged clinical beneficial effect on pain is far longer than the pharmacological effects of conduction blocks suggesting that local anesthetics may act on the pain mechanism⁶. Indeed this effect may be prolonged for several days to weeks^{7,8,9}. Only one study evaluated the effect of a single trigeminal nerve block (TNB) on quality of life. This study only included 6 patients and did not show a substantial improvement in quality of life 30 and 90 days after performing the block. Moreover, quality of life was a secondary objective of this study¹⁰. The main objective of the present study was thus to evaluate the effect of TNB on the quality of life 15 days after TNB in patients suffering from trigeminal neuralgia refractory to classically recommended clinical treatment. Secondary objectives were to evaluate the reduction in pain levels at 15 days as well as analgesic consumption, duration of block, and patient satisfaction.

Methods

This observational, descriptive, monocentric study was retrospectively performed in the postoperative pain clinic of a university hospital in patients receiving TNB between 2014 and 2018. Informed consent was obtained from patients after ethics committee approval (N° ID-RCB 2018-A01979-46) and ClinicalTrials.gov registration (NCT03669744).

Patients were included whenever they suffered from refractory trigeminal neuralgia and were referred from other pain clinics that did not perform such techniques. Patients received one or several blocks between 2014 et 2018 and were excluded when they declined to participate in the study, when they received another type of face block during the previous year, and in the case of insufficient data in the medical file or death at the time of the questionnaire. The telephone questionnaire was completed between July 2018 and March 2019.

During the first consultation, topography of neuralgia, complete neurologic examination and information on the procedure were assessed the by anesthesiologist and pain nurse. After patient consent, blocks were realized in conscious patients at the level of emergence of trigeminal nerve in the supra / infra zygomatic fossa or the supra orbital fossa as described by Pulcini et al.¹¹ A combination of 0.5% levobupivacaine, corticosteroid (cortivazol 3.75mg/1ml, or betamethasone 7mg/1ml when available) and $1\mu\text{g.kg}^{-1}$ clonidine were injected near the nerve trunk after a negative aspiration test. Patients were monitored 30 min following blocks in the post anesthesia room. Pain was evaluated before and 30 minutes after performing the block. Telephone follow-up calls were made 15 days following the last block.

Quality of life was evaluated before and at 15 days following nerve blocks by the SF-12 questionnaire in all patients. A cut-off value of less than 10% variation in their initial SF-12 score defined non-responders. Visual analogic pain score and DN4 scale quantified pain before and after nerve blocks. Patients were instructed to call to schedule a new block when pain reappeared. This time lag defined duration of analgesia. Patient satisfaction, analgesic consumption and adverse effects were evaluated at day 15.

Statistical analyses were done with XLSTAT software. Data obtained between day 0 and day 15 were compared by paired t-test. Linear regression analysis analyzed the link between SF-12 scores and other quantitative data and Cohen Kappa concordance tests. A p-value < 0.05 was considered statistically significant.

Results

Twenty-five patients received trigeminal nerve blocks between 2014 and 2018. Four patients were excluded : one died before inclusion, one remained unreachable, one refused to participate in the study and the last one had received another face block in the past year (Figure 1). Demographic and clinical data of the 21 remaining patients are given in Table 1 (62 ± 14 years ; sex ratio 0.6). Before performing nerve blocks, all patients received an anti-epileptic: 71% received carbamazepine, 76% amitriptyline and 95% an antidepressant. Fifty-two percent took an opioid among which 28% received morphine, fentanyl or oxycodone and 47% tramadol. Two patients had nerve surgery: thermocoagulation in one and micro-vascular decompression in the other. Patients had received an average of 4 TNB at the time of the study.

SF12 scores are shown in Figure 2. Eleven patients (52%) exhibited less than 10% increase in SF-12 PS and 12 patients (57%) in SF-12 MS. These patients were considered as non-responders. When excluding these non-responders, SF-12 PS increased by 16.6 points [12.1387 - 6.3033], $p < 0.01$, and SF-12 MS by 9.2 points [27.1476 - 6.0769], $p < 0.01$. No correlation was observed between SF-12 PS score with sex or age of patients, the time-lag between first symptoms and first block, or anatomical location of pain. SF-12 PS scores variation were correlated with patient satisfaction ($r^2 = 0.30$, $p = 0.01$) but not SF-12 MS ($p = 0.12$).

Pain was reduced by a mean of 3 points (t 4.578 ; IC 95% [1.8145 ; 4.8522] ; $p < 0.001$). Block efficacy was immediate on the neuropathic pain component with a mean 3 point decrease in the DN4 score (Figure 3). Block mean durations reached 15 ± 59 days with 1 and 90 days as extreme values. Patient satisfaction was correlated with block duration ($r^2 = 0.51$; $p < 0.01$). Among the 11 responder patients, 9 had a satisfaction score ≥ 7 . The 2 others had an unchanged SF-12 MS score. All non-responders had a satisfaction score ≤ 5 (Cohen Kappa concordance 0.81). Analgesic consumption and specifically opioid use was reduced by 61% between the first block and the time of the telephone questionnaire (Figure 4). Six adverse effects were observed: one diplopia, one edema at the puncture site, local dysesthesia on the block territory in one case, 3 cases of pain during puncture. In all cases, these effects were transitory. The block was considered as well tolerated according a visual analog scale of 7/10 rating experience as bad (0/10) to excellent (10/10).

Discussion

This retrospective monocentric study observed a significant mean improvement in quality of life according the SF-12 scale after TNB in 21 patients suffering from trigeminal neuralgia refractory to usual treatments. However, 50% of patients were non-responders to these blocks. When excluding these patients, the SF-12 PS score improved by 17 points to similar levels of a reference population. Improvement in quality of life was correlated with pain reduction, block efficacy and increased duration and patient satisfaction. Overall background pain therapies were reduced in half of the patients, and opioids in 63 %. Transitory minor adverse effects were observed in six cases but no major effects.

These results agreed with the only other study available on quality of life after TNB for refractory trigeminal neuralgia. This previous study was, however, performed in only 6 patients with trigeminal pain of heterogenous origin and used SF-36 quality of life questionnaires. In this latter study, quality of life scores were higher in the group which had already received blocks before receiving the blocks except for the “SF-36 physical role functioning” item. This item improved after blocks similarly to the SF-12 PS of the present study. We chose the SF-12 score because it is easy, rapid and feasible for a telephone interview. The EQ5D score was not performed despite its wide-spread use in the literature because it has a ceiling effect and a potential risk to under-detect small variations in quality of life. Variations in percentage to differentiate responders from non-responders was pragmatic because a minimal improvement threshold after loco-regional anesthesia has not been previously defined. Clinically pertinent SF-12 score improvements are heterogeneous in the literature. For example, in patients with lombalgia, 3 and 4 point variations in SF-12 PS may be considered clinically pertinent with lower values in patients with chronic pain and in those having a better quality of life¹². In contrast, after knee surgery, 9 and 14 point variations in SF-12 PS and MS are the threshold clinically pertinent values detected and only 1.5 to 2 points the minimal significantly detectable clinical variations in 90% of patients¹³. We considered in this paper that percentage variations were more pertinent than variations expressed as absolute values. Indeed, only a small increase in patients with a poor quality of life had a potentially higher impact than the same absolute variation in patients with a better basal quality of life. In this study, the good concordance between 10% improvement in SF-12 PS and patient satisfaction suggests that this 10% threshold was clinically pertinent.

Other factors than pain reduction may explain quality of life improvement or patient satisfaction. Empathic care in patients regarded as incurable or whose pain is disregarded is a major component of patient satisfaction¹⁴. In the present study, the lack of contentment or of SF-12 score improvement at day 15 when the TNB is ineffective suggest that this psychological component is not sufficient to explain SF-12 score improvement. This also argues against a placebo effect even if Bischoff et al. observed 40% of responders in the placebo group after ilio/hypogastric nerve blocks¹⁵. Reducing the number of treatments against pain that may reduce their adverse effects is also a major improvement factor in quality of life. In this study, at the time of the telephone questionnaire, opioid use was reduced by 63% and antiepileptic drugs by 48%.

Querying Pub Med from 2013 with MeSH terms « trigeminal nerve block », « peripheral nerve block », or « trigeminal neuralgia » found mainly isolated clinical cases or series presented in Table 2. Trigeminal neuralgia trigger-zone infiltration has only moderate efficacy on pain levels¹⁶. In all these papers, patient criteria of selection as well as type of blocks were heterogeneous leading to difficulties to compare with our results. In one study published only as an abstract in 2014, Calot et al.¹⁷ observed similar results with a 4 point mean VAS after performing face blocks in 44 patients and quality of life improvement in 82% of them without defining the SF-12 performance threshold. In one case Nader et al. in 2015⁸ observed a 50% reduction in pain levels, 15 days after performing a block on the V2 branch in a patient suffering from refractory trigeminal pain for 4 years. More recently, a retrospective study⁹ observed, analgesia lasting between 1 to 8 months after trigeminal nerve blocks in 6 out of 9 patients. In only one randomized study, quality of life was investigated in 13 patients suffering from trigeminal pain¹⁰. Six patients received TNB using 2% lidocaine injected in the supra/infra orbitary or mandibular foramina. At days 30 and 90, pain attacks were less frequent, pain levels reduced and quality of life improved according to the SF-36 questionnaire.

The combination used to perform the blocks in this study included 3 drugs : a long-lasting local anesthetic (0.5% levobupivacaine), a long-lasting corticosteroid and clonidine. The choice and doses of the drugs were based on routine practice, in order to prolong the duration of locoregional anesthesia and potentially act on chronic pain mechanisms as previously published¹⁸. The most frequently used treatment combines a local anesthetic and a long lasting corticosteroid (usually dexamethasone)^{3,8,19}. In many cases, when using very short action lidocaine, blocks lasted far longer than in the present study in which a long-acting local anesthetic was used. For example Cok et al.¹⁹ obtained a 21 month analgesia after a single infra-orbitary nerve block with 15 mg lidocaine and 1.5mg dexamethasone. In 2019, Gornitsky et al.²⁰ similarly observed several months pain relief in 3 patients after sphenopalatine nerve blockade with adrenaline-lidocaine. In the present study, block durations were not as long and were more variable when using a long lasting local anesthetic. Lidocaine neurotoxicity might explain these differences.

Corticosteroids are frequently used for chronic pain treatment either by local or perineural infiltration. They are effective for neuropathic pain relief²¹ and for prolonging analgesia after peripheral nerve blocks^{22,23}. Complete proof of their safety and absence of neurotoxicity are lacking. A recent anatomopathological study in mice, did not find Wallerian degeneracy nor perineural inflammation when dexamethasone was used alone or in combination with ropivacaine²⁴. Finally, in 2 meta analyses including 155 et 801 patients, no adverse effects were observed after perineural corticosteroid injection^{25,26}.

Clonidine perineural use is less common for chronic pain management. For example, Maranto et al.¹⁸, consider that potential benefits are higher than risks. Clonidine use is widely used for acute pain management with loco-regional anesthesia to increase and deepen analgesia²⁷ and prevent neuropathic pain²⁸.

Regardless of the combination used, long or short acting local anesthetics with or without adjuvants, analgesia is far longer than the sole conduction block induced by local anesthetics. Breaking the vicious

circle of chronic pain with locoregional anesthesia may partly explain the success of nerve blocks in chronic pain management.

Other therapeutic options including microvascular decompression and thermocoagulation are equally effective²⁹ but of longer duration³⁰. However, they require general anesthesia and sometimes repeated procedures to obtain optimal efficacy. Thirty to 45% of patients must continue medical treatment after surgery³¹. Prolonged adverse effects can be observed such as 15 to 50% sensory impairment³¹ and, although rare, mortality after microvascular decompression³⁰. After trigeminal alcoholization, 39 months relief was observed in a 465 patient retrospective cohort²⁹ but the complications rate reached 8.6% and all patients had some sort of sensory impairment. Trigeminal nerve blocks can be performed in an ambulatory setting, thereby avoiding general anesthesia and its complications and are well tolerated as measured in this study.

This study has several bias and limits. Trigeminal neuralgia is rare and 25% of patients can be refractory to a well conducted clinical treatment²³. This may explain why locoregional anesthesia efficacy is not fully demonstrated with regards to the low number of patients in the previous studies. Similarly, we included a limited number of patients leading to limited statistical power. Selection bias is unavoidable because 71% of patients were referred after ENT, dentistry or neurosurgery. In the present study population, post-traumatic trigeminal pain was over represented. The retrospective nature of the study engenders information and memorisation bias. Twenty per cent of patients in the present study had a depressive syndrome. The lack of correlation between the SF-12 PS and SF-12 MS scores before or after TNB confirms that performing the block is not sufficient and that specific psychological treatment is required. Specific depression-anxiety scales were not obtained for all patients and we did not correlate these scales with SF-12 MS scores.

Conclusion

This study demonstrated improved quality of life in patients suffering from refractory trigeminal pain fifteen days after specific nerve blocks. Half of patients were responders to this anesthetic technique and their quality of life was restored to similar levels compared to a reference population. This technique is simple, harmless and well accepted by patients. Further prospective multicentric studies are needed to confirm these results on quality of life, determine why some patients are unresponsive to this technique and to identify the best combination of drugs to inject in proximity to the nerves.

Nader et al. 2013 ³	Prospective cohort n = 15	Trigeminal nerve block in pterygopalatine fossa: Bupivacaine 0.25%+ Dexamethasone or Triamcinolone	Refractory trigeminal pain (2 weeks to 15 years) (V1, V2, V3)	low	Immediate : 80% Duration (days) 1st inj : 41j+/- 63 2 nd inj : 47j+/- 90 3th inj : 74j+/- 100 4th inj : 158 +/- 180	undone	none no local anesthetics intoxication	Blocks guided by echography Efficacy : Excellent ≥ 75% good 50 – 74% fair 25 – 49% low < 25% ↑ efficacy after repeated blocks
Nader et al. 2015 ⁸	Case report	Pterygo palatine fossa: Bupivacaine 0.25% + Dexamethasone	Refractory trigeminal pain (4years) (V2, V3)	low	Immediate : 100% Analgesia > 50% during 2 weeks	undone	none	Bocks guided by echography
Di Stani et al. 2015 ¹⁰	Randomized controlled study n = 13 Group 1 (control) : n=7 Group 2 : n=6 Evaluation at day 30 and 90.	G1 : oral treatment G2 : oral treatment + block Lidocaine 2% (2-4ml) Blocks at the Foraminal emergence	Refractory trigeminal neuralgia	medium	Frequency of pain attacks lower in G2	SF-36 G2 > G1	none	Symptoms older in group 2 BDI evaluation No significant difference
Takechi et al. 2015 ³²	Prospective cohort n = 6	Infra orbitary block Tetracaine 20mg + Bupivacaine 0,5% (0,5ml)	V2 Refractory trigeminal pain	low	3 months : n = 2 6 months : n = 2 permanent : n = 3 < 1 week : n = 3	Undone	2 minor hematoma at the puncture site Hypoesthesia > 2 weeks	Blocks guided by echography Tetracaine = neurolytic effect
Cok et al. 2017 ¹⁹	Case report	2 infra orbitary Blocs at 3 weeks intervall: Lidocaine 15mg + Dexamethasone 1,5mg	V2 Refractory trigeminal pain	low	At 21 months : ↓ NRS : 2 ↓ LANSS : 8	undone	none	Bocks guided by echography
Han et al. 2017 ²⁵	Retrospective cohort n = 465	Nerve alcoholization	V1, V2, V3 V2 Refractory trigeminal pain	low	Immediate : 99,4% Median duration : 39 months after the 1st block	undone	5,6% (paresthesia, dysesthesia, itching, ptosis, hypersialhorrea, mastication impairment, acouphens, diplopia 100% sensitive defect	alcoholization 33% recurrence after 1st block
Villar-Quiles et al. 2017 ³³	Prospective Cohort n = 7	Internal canthus infiltration Bupivacaine 0,5% (0,5ml)	V2 Refractory trigeminal pain	low	4/7 patients : 4 to 16 months 3/7 patients : recurrence < 48h	undone	none	
Perloff et al. 2018 ⁹	Retrospective cohort n = 9	Blocks at the 3 foramen sites Bupivacaine 0,25% (2ml) + Lidocaine 1% (1ml)	V1, V2, V3 V2 Refractory trigeminal pain	low	6/9 patients : 1 – 8 months	undone	undescribed	Emergency treatment
Gornitsky et al. 2019 ²⁰	Case serie n = 3	Greater palatine block (V2) Lidocaine 2% + epinephrine 1/100000 (1,8ml)	V2 Refractory trigeminal pain	low	Approximate duration > 12 mois > 50% reduction of oral pain treatment (carbamazepine)	undone	none	Main criteria of evaluation : antalgic consumption

BDI :Beck Depression Inventory, LANSS : Leeds Assessment of Neuropathic Symptoms and Signs Pain Scale, NRS : Numeric Rating Scale, SF-36 : Short Form 36.
