Brief Introduction

Reverse Transcription-Polymerase Chain Reaction (RT-PCR) is the gold standard for diagnosis of SARS-CoV-2 infection¹, but requires specialized equipment and reagents and suffers from long turnaround times. While valuable, chest imaging currently only detects COVID-19 pneumonia, but if it can predict actual RT-PCR SARS-CoV-2 status is unknown. Radiogenomics may provide an effective and accurate RT-PCR-based surrogate². We describe a deep learning radiogenomics (DLR) model (RadGen) that predicts a patient's RT-PCR SARS-CoV-2 status solely from their frontal chest radiograph (CXR).

Methods

The RadGen architecture, based on *SE-ResNeXt-50-32x4d*, was pretrained on ImageNet and ChestX-ray14 and 28,430 CXR from PadChest, and Kaggle before fine-tuned using CXR from a multinational cohort of RT-PCR tested patients from Hong Kong, GITHUB, SIRM and BIMCV (6,326 images)³⁻⁵. The model first predicted and selected only frontal CXR images, then predicted a segmentation mask of the cropped lung areas to reduce model fitting to unrelated parts of the image before using the segmented area as input for the RT-PCR SARS-CoV-2 binary classification task. The final prediction score was an ensemble consisting of the average of 4 models.

Results

RadGen achieved a mean Area Under the ROC curve (AUROC) of 0.959 (95%CI 0.955,0.962), sensitivity of 80.8% (3007/3723) and specificity 95.1% (16206/17033) using a pre-determined 0.4 cutpoint. It distinguishes pre-COVID-19, laboratory confirmed pneumonia from SARS2-CoV-2 cases with a specificity of 89.3% (225/252), and a specificity of 96.4% (106/110) on excluding SARS-CoV-2 infection on patients pre-COVID-19 CXR who later became RT-PCR positive.

The RT-PCR-tested cohort in Hong Kong consisted of 314 positive and 2,471 negative patients from 4 hospitals³. The SARS-CoV-2 positive patients had a median of 9 (range 3-24) RT-PCR tests and 3 corresponding (range 1-8) CXR during their hospitalization (range 3-112 days); 90.8% (285/314) had mild/asymptomatic disease. The sensitivity and specificity of RadGen for predicting SARS-CoV-2 infection on initial presenting CXR was 79.5% (225/283) and 85.2% (2105/2471).

RadGen time course analysis by autocorrelation function (ACF) plot, which describes how well RadGen predicts a patient's RT-PCR SARS-CoV-2 status over the course of their entire

SARS-CoV-2 infection period, was performed revealing a peak lag at 2 days for radiogenomic signature manifestation on CXR after initial RT-PCR diagnosis. The per-film false negative rate was 10.0% (26/261) and 9.3% (21/225) within and after 7 days of the first RT-PCR positive test with a false positive rate of 68.1% (32/47) and 11.3% (45/397) within and after one week of achieving RT-PCR confirmed viral clearance (Fig 1).

Comment

Leveraging a DLR strategy and a rich body of training datasets including Asian and Western countries (reflecting a diverse set of clinical containment protocols), a wide spectrum of clinical presentations including mild and asymptomatic disease, and a prospectively collected multi-timepoint RT-PCR SARS-CoV-2 positive patient cohort, we generated a DLR model capable of predicting a patient's RT-PCR status from CXR.

Interestingly, we also show that RadGen can non-invasively 'track' RT-PCR SARS-CoV-2 status over the course of their infection, from diagnosis to viral clearance. A time-delayed correlation between RadGen and RT-PCR seen at the time of initial RT-PCR positivity and at the time of achieving RT-PCR viral clearance was observed. This is not unexpected as SARS-CoV-2 genomic dosage changes have been shown to take time to accumulate and be phenotypically reflected on a cellular, organ and systems level. Further, it is known that SARS-CoV-2 RNA can persist long after active infectivity and symptom resolution⁶; thus, that RadGen performs this well, particularly in a mild/asymptomatic cohort, is notable.

In conclusion, the feasibility for DLR models to dynamically track RT-PCR SARS-CoV-2 changes on an individual level significantly expands the scope of radiogenomics.
