Abstract

Policy responses to COVID-19, particularly those related to non-pharmaceutical interventions, are unprecedented in scale and scope. Researchers and policymakers are striving to understand the impact of these policies on a variety of outcomes. Policy impact evaluations always require a complex combination of circumstance, study design, data, statistics, and analysis. Beyond the issues that are faced for any policy, evaluation of COVID-19 policies is complicated by additional challenges related to infectious disease dynamics and lags, lack of direct observation of key outcomes, and a multiplicity of interventions occurring on an accelerated time scale.

In this paper, we (1) introduce the basic suite of policy impact evaluation designs for observational data, including cross-sectional analyses, pre/post, interrupted time-series, and difference-in-differences analysis, (2) demonstrate key ways in which the requirements and assumptions underlying these designs are often violated in the context of COVID-19, and (3) provide decision-makers and reviewers a conceptual and graphical guide to identifying these key violations. The overall goal of this paper is to help policy-makers, journal editors, journalists, researchers, and other research consumers understand and weigh the strengths and limitations of evidence that is essential to decision-making.

Introduction

The response to the global COVID-19 pandemic has demanded urgent decision making in the face of substantial uncertainties. Policies to arrest transmission, including stay-at-home orders and other non-pharmaceutical interventions (NPIs), have wide-reaching consequences that touch many aspects of well being. Decision-making in the public interest requires evaluating and weighing the evidence on both intended and unintended consequences in order to best predict outcomes. The wide range of policy interventions implemented by different jurisdictions may yield opportunities for learning from what has already happened to inform future policymaking, and we have observed a proliferation of studies aimed at such policy evaluations. However, policy evaluation requires a complex combination of circumstance, data, study design, analysis, and interpretation in order to be informative.

Policy impact evaluation aims to answer questions about the extent to which the realized outcomes given a particular policy would have been different in the absence of that policy. Estimating the causal impact of the policy with observational data is challenging because what would have happened in the absence of the policy change (the “counterfactual”) is, by definition, unobserved. Randomized controlled trials (RCTs) of policies related to COVID-19 interventions may not always be practical or ethical. In this context, a large and growing number of studies have attempted to evaluate the impact of COVID-19 policies using observational data. There
are many potential pitfalls in the use of observational data for evaluation generally, and some additional methodological design challenges relating to COVID-19 policies in particular.

This paper provides a graphical guide to policy impact evaluations for COVID-19, targeted to decision-makers, researchers and evidence curators. Our aim is to provide a coherent framework for conceptualizing and identifying common pitfalls in COVID-19 policy evaluation. Importantly, this should not be taken either as a comprehensive guide to policy evaluation more broadly or as guidance on performing analysis, which may be found elsewhere. Rather, we review relevant study designs for policy evaluations — including pre/post, interrupted time series, and difference-in-difference approaches — and provide guidance and tools for identifying key issues with each type of study as they relate to NPIs and other COVID-19 policy interventions. Improving our ability to identify key pitfalls will enhance our ability to identify and produce valid and useful evidence for informing policymaking.

Common policy evaluation designs and their pitfalls in COVID-19

* Assessing both slope and level only applicable if there are multiple data points during the post period

† Units without the intervention may be the pre-period of a different unit that eventually receives the intervention.

Identifying the underlying design in a given analysis often requires using a combination of the methods as reported and evaluating the data structure that is used for the main analysis, as shown in Table 1. COVID-19-related policy evaluation analyses typically fall under these categories. In most cases, the design can be categorized using a combination of whether there are also units that did not receive the treatment (columns 2-3) and whether there are time points both before and after intervention for those units (columns 4-5). The final column describes the implied counterfactual, discussed further in subsequent sections. Cross sectional designs typically compare units with vs without the treatment at single time points. Pre/post studies typically compare within units who received the intervention at two points: before and after a policy. Interrupted time-series analyses compare outcomes within units within units who received the intervention at greater than two time points before the intervention vs with at least one (typically multiple) after the intervention. Difference-in-differences analysis compares the outcome change in units which received the intervention with those that did not (or have not yet), with at least one point before and one after the intervention. In cases with multiple periods, that may involve a comparison with the pre-policy period of one region with the post-period of a different region, even though all regions eventually receive the intervention.
Methods descriptions may not always provide a precise or reliable guide to which of the design approaches has been used. Some studies do not explicitly name these designs (or may classify them differently); and these are only a small fraction of designs and frameworks that are possible to use for policy evaluation. Studies may have data at multiple time points but are effectively cross-sectional. DiD, ITS, and CITS designs based on repeated cross-sectional data are sometimes described as "cross-sectional" instead of longitudinal. The term "event study" is often used to refer to studies with a single unit and one change over time resembling ITS, but may refer to other designs. Although ITS is often used to describe changes in one unit, it may also refer to settings in which many treated units adopt an intervention over time. Studies will also frequently employ multiple designs, while others use more complex methods of generating counterfactuals. Definitions of these terms vary widely, and the definitions above should be considered as guidance only.

Policy impact evaluation design foundations for COVID-19

The simplest design is the cross-sectional analysis, which compares COVID-19 outcomes between units of observation (e.g., cities) at a single calendar time or time since an event, typically post-intervention. These studies are unlikely to be appropriate for COVID-19-related policy evaluations, but provide a useful starting point for reasoning about different designs. Just as with comparisons of non-randomized medical treatments, the localities that adopt a particular policy likely differ substantially from those that don't on both observed and unobserved characteristics on a number of dimensions, including epidemic status and timing.

Figure 1: Longitudinal designs overview
This chart shows four canonical longitudinal designs. In all cases: the blue shading represents the underlying data trends, the solid vertical grey line represents the time of intervention, the grey dashed lines represent the assumed counterfactual in the absence of the intervention, as discussed in the text. The impact estimate is obtained by comparing the outcomes observed for the treated unit in the post period (the solid line) with the implied counterfactual line (the dashed line). In the case of the pre/post and
difference-in-differences panels the large black dots represent the time of measurement, connected by the grey dotted lines.

Given the challenges in a simple cross-sectional comparison, which compare post-intervention outcomes, it is important to consider longitudinal designs, which instead look at differences or trends across time, as summarized in Figure 1. These can be distinguished by the data used and the construction of the counterfactual. Pre/post, for example, has only one unit, measured at two time points. Two common strategies expand on the logic and data requirements of the pre/post design. Interrupted time series designs (Figure 1B) incorporate multiple time points before the intervention, and usually multiple time points after the intervention, to enable a more complete view on changes in levels and trends that are temporally related to the intervention. Difference-in-difference designs (Figure 1C) add a set of comparison points from a group or location that did not have the intervention. Another related design (comparative interrupted time-series, Figure 1D, discussed only briefly here), uses both aspects — a change over time and a comparison group — to compare the observed change in slopes for the intervention group with the change in slope for the comparison group.

Pre/post studies

The simplest longitudinal design is a pre/post analysis, where some outcome is observed before policy implementation, and again after, in a single group (Figure 1A). Pre/post studies are analogous to a single arm trial with no control and only a single follow-up observation after treatment. This effectively imposes the assumption that the counterfactual trend is completely flat (i.e., that the outcome in the post-period in the absence of the policy change is the same as the value of the outcome before the policy change) without accounting for pre-existing underlying trends, and attributing all outcome changes completely to the intervention of interest. Just as the outcomes for an individual patient might be expected to change before and after treatment, for reasons unrelated to the treatment, outcomes related to policy interventions will change for reasons not caused by the policy. Infection rates, for example, would not be expected to remain stationary except in very specific circumstances, but a pre/post measurement would assume that any changes in infection rates are attributable to the policy.

Interrupted time-series

Figure 2: Interrupted time-series graphical guidance for identifying common pitfalls.
Interrupted time-series (ITS) is a strategy that uses a projection of the pre-policy outcome trend as a counterfactual for how the outcome would have changed if the policy had not been introduced. In other words, in the absence of the policy change, ITS assumes the outcome would have continued on its pre-policy trend during the study period. ITS can be a useful tool in policy evaluation because it allows researchers to account for underlying trends in the outcome and, by comparing the treated unit (or location) to itself, it can therefore eliminate some of the confounding concerns that arise in cross-sectional or pre-post studies.

However, the validity of ITS depends critically on how well counterfactual trends in the outcome are modelled, and whether the policy of interest is the only relevant change during the study period. In the canonical setting (Figure 2A), the pre-policy trend is stable and can be feasibly modelled with the available data; the researcher appropriately models the timing of the change in the slope and/or level of the outcome; the researcher has sufficient information to conclude...
that there were no other changes during the study period that would be expected to influence the outcome. These elements are largely not satisfied in studies of COVID-related policy, as described below.

ITS relies critically on modelled trends of the outcome over time. Key components of ITS analyses include both visual and statistical examination of trends, preferentially alongside a theoretical justification of the model used. At a minimum, analyses should provide graphical representation of the data and model over time to examine whether pre-trend outcomes are stable, all trends are well-fit to the data, “interrupted” at the appropriate time point, and sensibly modelled (Figure 2B). In the case where an ITS includes a large number of units (e.g. states), it can be difficult to display this information graphically.

One common pitfall in ITS is adoption of inappropriate assumptions on the outcome trend (Figure 2C). The estimate of policy impact will be biased if a linear trend is assumed but the outcome and response to interventions instead follow nonlinear trends (either before or after the policy). In some cases, transformation of the outcome, for example using a log scale, may improve the suitability of a linear model. Imposing linearity inappropriately is a serious risk in the context of COVID-19, as trends in infectious disease dynamics are inherently non-linear. For intuition, terms such as “exponential growth,” “flattening,” and “s-curves” all refer to non-linear infectious disease trends. Depending on the particular situation, non-linearity or other modelled trends can have complicated and counterintuitive impact on policy impact. Apparent linearity may also be temporary and an artifact of testing, which may give a misleading impression that linear models for infectious disease trends are appropriate indefinitely. While some use linear progression in order to avoid more complex infectious disease models, in fact, linear projections impose strict and often unrealistic models, generally resulting in an inappropriate counterfactual.

Researchers can easily misattribute the timing of the policy impact, resulting in spurious inference and bias (Figure 2D). Some public health policies can be expected to translate into immediate results (e.g., smoking bans and acute coronary events). In contrast, nearly every outcome of interest in COVID-19 exhibits complex and difficult to infer time lags typically in the realm of many weeks. The time between policy implementation and expected effect in the data can be large and highly variable. For example, in order to see the impact of a mask order, first the mask order takes effect, then people change their behaviors over time to comply with the order (or sometimes the reverse in the case of anticipation effects), mask use behavior produces changes in infections, then infections later result in symptoms, symptoms induce people to seek testing, the tests must then be processed in labs, and then finally the results get reported in data monitoring efforts. Selection of lead/lag time should be justifiable \textit{a priori} or external data. Selecting a lag based on the data risks issues comparable to p-hacking.

Finally, and perhaps most concerningly in the context of COVID-19, ITS fails when the policy of interest coincides in time with other changes that affect the outcome (Figure 2E). For example, if both mask and bar closure orders are rolled out together as a package, ITS cannot isolate the impact of bar closures specifically. These changes do not need to have taken place exactly
concurrently with the policy implementation date of interest; they merely need to have some
effect within the time period of measurement to result in potentially serious bias in effect
estimates if unaddressed. ITS will also likely be biased if, during the study period, there is a
change in the way the outcome data is collected or measured. This might occur if the
introduction of a COVID-19 control policy is combined with an effort to collect better data on
infection or mortality cases. Analogously, if an RCT involves randomizing people to a group
receiving both A and B vs. control, we typically can't disentangle the effects of A from the effects
of B, unless we also have separate A- and B-only arms. Ultimately, if multiple things are
changing at the same time, ITS may not be an appropriate design for policy evaluation.

COVID-19 policies rarely arrive alone; they are typically created alongside other policies,
onofficial action, and large scale behavior changes which themselves impact COVID-19-related
outcomes. In some cases, anticipation of a policy may induce behavior change before the actual
policy takes effect. The policies themselves may have been chosen due to the expectation of
change in disease outcomes, which introduces additional biases related to “reverse” causality.

**Difference-in-differences**

The difference-in-difference (DiD) approach uses concurrent non-intervention groups as a counterfactual. Typically, this consists of one set of units (e.g., regions) that had the intervention and one set that did not, with each measured before and after the intervention took place. DiD is more directly analogous to a non-randomized medical study with at least one treatment and control group but limited observation before and after treatment. In contrast to ITS, which compares a unit with itself over time, DiD compares differences between treatment arms or units at two observation points. In many analyses, a DiD approach is implied by comparing regions over time, without formally naming or modelling it. Other DiD approaches use interventions implemented at multiple time points.

Figure 3: Difference-in-differences graphical guidance for identifying common pitfalls
This chart shows one canonical design for DiD (blue, Panel A) and four panels demonstrating common issues with DiD analysis (red, panels B-E). In all cases: the blue/red shading represents the underlying data trends, the vertical grey line represents the time of intervention, the grey dashed lines represent the assumed counterfactual in the absence of the intervention. In panel D) the dash-dot line represents the time at which the policy is expected to impact the outcome. In panel E), the vertical dotted lines represent concurrent events and changes.

One key component of the standard DiD approach is the parallel counterfactual trends assumption: that the intervention and comparison groups would have had parallel trends over time in the absence of the intervention. In some cases, the parallel trends assumption may be referenced or examined implicitly but not named.

Ideally, pre-intervention trends would be shown to be clearly identifiable, stable, of a similar level, and parallel between groups. With only one observation before and only one after the intervention, assessment of the plausibility of the parallel counterfactual trends assumption is not possible. Absent this confirmation the evaluation runs the risk of biased estimation due to differential pre-trends (Figure 3B). Pre-trends approaching the ceiling or floor may also not be informative about stable and parallel pre-trends. Empirical assessment of whether pre-intervention trends were parallel and stable between groups is possible when multiple observations are available at multiple time points before the intervention, noting that this can
begin to resemble a CITS design. In this scenario, pre-trend data should be visually and statistically established and documented. While parallel trends before intervention (which we can observe and may be testable) do not guarantee parallel counterfactual trends in the post-intervention period (which we cannot observe and are generally untestable), examining pre-intervention parallel trends is a minimal requirement for DiD reliability.

It is also important to consider the scale and level on which the outcome is measured (Figure 3C). As with ITS, if the outcomes in the treatment and comparison groups are moving in parallel on a logged scale, they will not be moving in parallel on a natural scale. Level differences by themselves may be a problem for COVID-19 outcomes, as infectious disease transmission dynamics dictate that infection risks are related to the prevalence of infected people in a population, i.e. the rate of change is linked intrinsically to the level. A population with an extremely low prevalence will tend to have an inherently slower rise in infection rates than an otherwise identical population with merely a low prevalence. Just as importantly, large level differences in the outcome between intervention and comparison groups is often indicative of other important differences between comparators, which may result in other assumptions being violated.

While DiD is in some ways more robust to very specific kinds of timing effects (Figure 3D) and concurrent changes (Figure 3E), it also introduces additional risks. DiD effectively doubles the opportunity for concurrent changes to spuriously impact results, since they can occur in the treatment or comparison groups. As above, this can become even more problematic for DiD in the typical case where intervention groups enact more or very contextually different policies than non-intervention groups. Even cases where concurrent changes happen equally in both treatment and comparison groups can lead to overwhelming bias, particularly when approaching the maximum or minimum levels of the outcome. If either the treatment or control group is approaching the floor (e.g. 0% prevalence) or ceiling for an outcome of interest due to other policies concurrent in both places (e.g. national lockdowns, but region-level differences in mask policy), this can lead to bias when comparing changes between the two groups.

Similarly to the ITS section, these issues are summarized as a checklist of questions to identify common pitfalls in Table 3.

### Discussion

In recent months, there has been a proliferation of research evaluating policies related to the COVID-19 pandemic. As with other areas of COVID-19 research, quality has been highly variable, with low quality studies resulting in poorly or mis-informed policy decisions, wasted resources, and undermined trust in research. To support high quality policy evaluations, in this paper we describe common approaches to evaluating policies using observational data, and describe key issues that can arise in applying these approaches. We hope that this guidance can help support researchers, editors, reviewers, and decision-makers in conducting high quality policy evaluations and in assessing the strength of the evidence that has already been published.

Policy evaluation — far from a simple task in normal circumstances — is particularly challenging during a pandemic. Cross-sectional comparisons of states or countries are likely to be biased by selection into treatment: for example, countries with worse outbreaks may be more likely to
implement policies such as mask requirements. In analyses of changes over time – such as single-unit studies using interrupted time-series or multi-unit comparisons using difference-in-differences or comparative interrupted time-series – it may not be possible to parse apart the effects of different policies implemented around the same time, such as mask mandates paired with limits on social gatherings. Analyses of changes over time may also be biased if disease or human behavioral dynamics are not modelled appropriately. This can be challenging because case counts typically do not grow linearly and there is often a lag between a policy change and a behavioral response.

This guidance should be considered minimal screening to identify low quality policy impact evaluation in COVID-19, but is in no way sufficient to identify high quality evidence or actionability. Decision-makers and researchers should pay particular attention to the relevance of the intervention as it was evaluated to relevant decisions being made. The evaluated impact of a program encouraging mask use through messages might not be informative about mask requirement orders. Differences in level of aggregation may be important, such as ecological fallacy arising from a situation in which areas with higher overall mask use have higher transmission, but transmission is actually lower for individuals wearing masks. Policy impact evaluation is only as useful as the question it asks, data it uses, and the way it is analyzed. Problems with measurement, spillover effects, generalizability, changes in measurement overtime (e.g. varying test availability), statistics, testing robustness to alternative assumptions, and many issues can undermine an otherwise robust evaluation, and are not discussed here.

While this guidance is not comprehensive, it may help inform study designs not covered here. Issues with comparative interrupted time-series and synthetic control methods, for example, are broadly similar to the issues with difference-in-differences analyses we discuss here. Other approaches may include adjustment and matching based observational causal inference designs, instrumental variables and related quasi-experimental approaches, and randomized controlled trials. Each has its own set of practical, ethical, and inferential limitations.

In the face of these challenges, we recommend careful scrutiny and attention to potential sources of bias in COVID-19-related policy evaluations, but we remain optimistic about the potential for robust evaluations to inform decision-making. Researchers and decision-makers should triangulate across a large variety of approaches from theory to evidence, invest in better data and more reliable and useful evidence wherever feasible, clearly acknowledge limitations and potential sources of bias, and acknowledge when actionable evidence is not feasible. We anticipate increasing opportunities for better examining policies moving forward, particularly if policies and interventions are designed with policy impact evaluation and data collection in mind.

The COVID-19 pandemic requires urgent decisions about policies that affect millions of people's lives in significant ways. High quality evidence on the effects of these policies is critical to informing decision-making, but is very hard to generate. Evidence-based decision-making
depends on research that carefully considers potential sources of bias, and clearly communicates underlying assumptions and sources of uncertainty.
