7 Abstract

8 The human leukocyte antigen (HLA) system is the single most important genetic
9 susceptibility factor for many autoimmune diseases and immunological traits.
10 However, in a range of clinical phenotypes the impact of HLA alleles or their
11 combinations on the disease risk are not comprehensively understood.

12 For systematic population-level analysis of HLA-phenotype associations we
13 imputed the alleles of classical HLA genes in a discovery cohort of 146,630 and
14 replication cohort of 89,340 Finns of whom SNP genotype data and 3,355 disease
15 phenotypes were available as part of the FinnGen project.

16 The results suggest HLA associations in phenotypes not reported previously and
17 highlight interactions between HLA genes and alleles in autoimmune diseases.
18 Furthermore, shared HLA alleles in autoimmune and infectious diseases support
19 a genetic link between these diseases.

20 Introduction

21 Regulation of adaptive immune system function is based on recognition of
22 foreign antigens and infectious agents by human leukocyte antigen (HLA)
23 receptors encoded by highly polymorphic loci within the major histocompatibility
24 complex (MHC) on chromosome 6. Out of more than 200 genes harbored by the
25 MHC region approximately half have known immune-related functions (The MHC
26 sequencing consortium, 1999). The HLA molecules play a key role in the
27 initiation of immune response by binding internal (HLA class I molecules *A*, *B*, *C*)
28 and external (HLA class II molecules *DR*, *DQ*, *DP*) peptides and presenting them
29 to T lymphocytes. While class I receptors present antigens directly to cytotoxic
30 CD8+ T cells, the class II molecules are recognized by CD4+ T cells that polarize
31 into different regulatory subtypes (A. Barr et al., 2012). The extremely high
32 genetic polymorphism of HLA genes results in structural variation in the peptide
33 binding pockets between HLA alleles, consequently leading to different peptide-
34 binding preferences and varying antigen repertoires presented to T cells.

35 Originally discovered over 50 years ago as the major determinant of organ and
36 hematopoietic graft rejection (Thorsby, 2009), genetic variation in HLA has since
37 been linked to a wide spectrum of immunological diseases (Trowsdale and
38 Knight, 2013). In major multifactorial autoimmune diseases, HLA alleles and their

protein-level motifs present the most important single genetic component in disease susceptibility (Matzaraki et al., 2017), even though in most diseases the triggering peptide complexing with the implicated HLA protein polymorphism remains unknown (Dendrou et al., 2018). On the other hand, varying degrees of protective allelic effects as distinguished from the absence of strong susceptibility alleles have been reported for major autoimmune disorders (Bettencourt et al., 2015; van der Helm-van Mil et al., 2005; van Lummel et al., 2019). The effect towards the reduction of disease risk is presumably mediated through presentation a favourable selection of antigens in terms of specificity and self-regulation (Tsai and Santamaria, 2013). Accordingly, both susceptibility and resistance effects have been attributed to amino acid residues and their positions in the HLA protein sequence (Furukawa et al., 2017; Gregersen et al., 1987; Raychaudhuri et al., 2012). Different alleles sharing a similar structural motif also manifests in local epistasis. Detailed analyses of large cohorts of patients with rheumatoid arthritis or type 1 diabetes have demonstrated that the MHC-mediated risk can be pinpointed to specific amino acid positions, and the effect is being modified non-additively by amino acid polymorphisms in a few other positions in the same or different class II gene (Hu et al., 2015; Lenz et al., 2015; Okada et al., 2016).

HLA allelic variance can cause differences in the strength of immune response against infectious agents such as HIV by differential preference of viral peptides (The International HIV Controllers Study, 2010). However, in case of structural similarity between pathogen T cell epitope and a host peptide, immune reaction against the antigen may also increase the likelihood of developing autoimmunity (Oldstone, 1998). Predisposition to infections before the onset of an autoimmune condition has been reported in several cases (Sfriso et al., 2010), and reaction of host T cell clones against the pathogen epitope mimicking host structures has been demonstrated experimentally (Wucherpfennig and Strominger, 1995). Nevertheless, exposure to a rich microbial environment also contributes to achieving protective, tolerogenic setting through toll-like receptor, regulatory T cell and interleukin signaling (Bach, 2018). Immunological regulation and its perturbation are therefore dependent on both environmental and host genetic factors that are mediated by individually varying HLA presentation.

Large biobank genome data collections combined with electronic health records have made phenome-wide association studies (PheWAS) feasible (Denny et al., 2013), leading to increased power and novel discoveries in disease genetics

(Diogo et al., 2018; Liu et al., 2016; Verma et al., 2018). Population-based approach for the analysis of phenotypic spectrum of HLA associations can give novel insights into the architecture of well-established autoimmune and immune disease associations and broaden the view toward other traits as well (Hirata et al., 2019; Karnes et al., 2017; Liu et al., 2016). The first reported HLA PheWAS analysis with over 11,000 individuals found eight novel phenotypes linked with MHC SNPs as well as five previously unknown associations across multiple phenotypes (Liu et al., 2016). Karnes and coworkers (2017) imputed HLA alleles from cohorts of 28,839 and 8,431 individuals of European origin and tested HLA associations with 1,368 phenotypes. 104 significant associations were observed with 29 phenotypes and 29 HLA alleles. In addition to well-established HLA associations, four novel phenotypes were reported. Hirata and coworkers (2019) analyzed 106 clinical phenotypes for association with MHC variation in a cohort of 166,190 individuals from Japan. They reported significant genotype-phenotype associations in 52 phenotypes, and their fine-mapping showed multiple different patterns of HLA associations, some of which were independent from classical HLA genes.

Here we report a systematic, population-based association study of imputed HLA alleles in 3,355 phenotypes in discovery and replication cohorts of 146,630 and 89,340 individuals, respectively. These large single-population cohorts enabled us to perform HLA analysis in diseases not studied in detail before and to reveal cross-phenotype dependencies of allelic associations particularly between autoimmune and infectious diseases. Furthermore, as a systematic examination of risk-modifying effects have not, to our knowledge, been implemented at biobank-scale to date, we sought to define protective allelic effects as opposed to nonpredisposition to the top risk alleles. To this end, we studied heterozygous risk allele genotypes, and hypothesized that a risk allele effect could also be modified by a HLA locus of a different class.

Results

Associations of imputed HLA alleles

Altogether 155 four-digit HLA alleles were imputed with posterior probability > 0.5, and of these, 84 alleles had at least one confirmed association in both cohorts. In total, we found 3,649 statistically significant HLA-allele-phenotype

associations in 368 phenotypes (Supplementary Table 1). Supplementary Figure 1 summarises the distribution of allele associations across the main phenotype categories for each HLA gene. HLA class II genes harboured both the largest number of associations and the strongest associations as indicated by their effect sizes. The top disease categories in terms of number of associations were type 1 diabetes and rheumatic diseases. We did not find a relationship between the number of significant associations and the number of available cases in a phenotype (Supplementary Figure 2).

1,620 of the 3,649 replicated HLA associations were in diabetes-related traits (Supplementary Table 1) with *DQB1*03:02* as the top risk allele. Celiac disease (CD) had the second highest number of HLA associations. The lowest p-values were for *DRB1*03:01*, *DQA1*05:01* and *DQB1*02:01* followed by other alleles known to be in a strong linkage disequilibrium with this HLA class II haplotype.

To validate our analysis we compared our results with previously published HLA PheWAS studies (Hirata et al., 2019; Karnes et al., 2017; Liu et al., 2016). We observed a consistent relationship between the obtained odds ratios of associated HLA alleles or genes and those of the three other previously published HLA PheWAS studies (Figure 1a). Further, to evaluate the consistency of associations between the discovery and replication cohorts, we correlated the logistic regression log-odds ratios (betas) for the three types of analysis implemented here: HLA allele, diplotype and haplotype. Expectedly, we observed a strong correlation between the two independent cohorts (Pearson's correlation coefficient about 0.9; Figure 1b).

We discovered statistically significant (discovery FDR < 0.01, replication p < 0.01) HLA allele associations in seven phenotypes for which we found scarce prior evidence of HLA association in the literature (Table 1). For example, we observed an association for *DQA1*01:03* and *DQB1*06:03* in mental and behavioural disorders due to cannabinoids (p-value = 10^{-5} ; beta = 0.6). Moreover, drug-induced hypoglycaemia without coma, vitreous haemorrhage, otitis externa, acute sinusitis, and trigger finger were all associated with *DQB1*03:02* and scleritis and episcleritis was associated with *B*27:05*.

Figure 1. Comparison of HLA association effects. **a)** Odds ratios of previously reported HLA PheWAS associations (x-axis) vs. the discovery cohort of the present study (y-axis). Depending on the study, associations are shown either at the level of four-digit alleles (Karnes *et al.*) or at gene-level tagged by the highest ranking variant (Liu *et al.* & Hirata *et al.*). **b)** Correlation of HLA association FDR < 0.01 log-odds ratios (betas) between the discovery cohort (x-axis) and the replication cohort (y-axis) of the present study. Panels from left to right show the data for HLA allele, genotype, and two-locus haplotype association analyses.

Table 1. HLA allele associations and modifying effects in previously poorly studied phenotypes. Diplotype and haplotype analyses show effects of combinations of two alleles. Here, a strong protective effect on the risk allele can result in non-significant association.

Type of analysis	Phenotype	Primary HLA	Modifying HLA	Discovery			Replication	
				p-value	Beta	SE	Beta	SE

^a Protective effect was determined relative to this allele combination in diplotype and haplotype analyses.

Cross-phenotype HLA allele associations

To evaluate possible independence of an HLA association between two phenotypes, we conducted analyses by including a phenotype as an additional covariate in the regression models. We observed that altogether 68 HLA alleles showed evidence of independent association with two or more phenotype categories (Supplementary Table 2). To study shared HLA associations in autoimmune and infectious diseases, we narrowed down the results for these phenotypes to include only alleles that in conditional analyses showed evidence of associating with infectious diseases independently of at least one autoimmune disease. The results are summarized by Figure 2, showing the alleles, p-values, phenotypes and effect sizes of the associations. We found 12 alleles in five infectious and five autoimmune diseases that fulfilled the above criteria of association. Nine HLA alleles, eight of which appeared to be parts of *C*07:01 - B*08:01 - DRB1*03:01 - DQA1*05:01 - DQB1*02:01* and *DRB1*04:01 - DQA1*03:01 - DQB1*03:02* haplotypes, as well as *B*13:02*, predisposed to both autoimmune diseases and infections. Three alleles, all part of the *DRB1*13:01 - DQA1*01:03 - DQB1*06:03* haplotype, showed a lower frequency in cases. Altogether ten alleles associated with two or more infectious-autoimmune disease pairs.

HLA diplotype associations

To analyze the effect of HLA risk allele diplotypes on the level of disease susceptibility, we conducted conditional regression analyses with diploid allele combinations. We found 225 statistically significant (discovery FDR < 0.01, replication p < 0.01) phenotypes representing 21 different phenotype categories associated with at least one risk allele diplotype (Supplementary Table 3). In 91 phenotypes representing 13 different phenotype categories the other HLA allele in the same locus exerted a statistically significant (discovery FDR < 0.01, replication p < 0.01) modifying effect on the risk allele (Supplementary Table 4). Figure 3 shows significant modifying allelic effects in phenotypes that deviated the most from expectation (i.e. the sum of individual allele effects, Figure 3a). For example, in type 1 diabetes, the results replicated the well-established protective allele *DQB1*06:02* and showed that *DQB1*04:02* increased the *DQB1*03:02* mediated risk for insulin medication despite having negative effect

185 direction (-0.16) in the allele-level association analysis (Figure 3b). In coeliac
186 disease, alleles such as *DQB1*06:03* or *DQB1*04:02*, that showed negative beta
187 values in the single allele association test, contributed towards increasing the
188 *DQB1*02:01* mediated risk (Figure 3b). Potentially novel heterozygotic effects on
189 the risk allele are listed by Table 1.

190 **Figure 2.** HLA alleles associated with an infectious disease independently of
191 autoimmune disease. **a)** P-values of significant ($< 5 \times 10^{-8}$) alleles. Each panel
192 show an infectious disease phenotype. Within panels, one allele can associate
193 with more than one autoimmune disease. **b)** HLA alleles associated with
194 infectious diseases (y-axis) independently from autoimmune diseases (x-axis).
195 The color-filled squares indicate the effect size and direction. The results are
196 grouped by known haplotypes in each row. DQA1*05:01 is omitted from the first
197 row as its profile is identical to the other two shown class II alleles. The data are
198 based on conditional regression analyses with $p < 5 \times 10^{-8}$ threshold in the full
199 dataset (discovery+replication), where selected phenotypes were analysed by
200 adding a different phenotype as an additional covariate in the model one at a
201 time.

Figure 3. HLA diplotype effects. Risk allele in combination with the second allele of the same HLA gene. **a)** Phenotypes in which the risk allele diplotype association effects deviate from expected (i.e. sum of individual allelic effects). **b)** The x-axis shows log-odds ratios (betas) for different diplotypes depicted on the y-axis. The y-axis label indicates the primary risk allele, and the tick mark labels indicate the other alleles in the same locus. The vertical dashed lines indicate the risk allele's effect estimates based on allele-level analysis. Only significant (discovery FDR < 0.01, replication p < 0.01) effects on the risk allele are shown. The error bars indicate standard errors for the beta values.

211 HLA haplotype associations

212 To test whether the effect of a primary risk allele was affected by alleles of a HLA
 213 gene of a different class, we conducted conditional regression analyses with
 214 allele combinations from two HLA genes (termed here as haplotype
 215 associations). The analysis was performed using phased data but we cannot
 216 prove that they genuinely formed haplotypes. We found a total of 16 statistically
 217 significant haplotype associations with 224 phenotypes representing 23 different
 218 phenotype categories (Supplementary Table 5). There was a statistically
 219 significant (discovery FDR < 0.01, replication p < 0.01) modifying effect on the
 220 risk allele in 56 phenotypes representing 10 phenotype categories
 221 (Supplementary Table 6). Figure 4a shows significant modifying allelic effects in
 222 phenotypes that deviated the most from expectation (i.e. the sum of individual
 223 allele effects). For example, in T1D, even though *B*44:27* by itself was not
 224 associated, together with *DQB1*03:02* the risk is increased (Figure 4b).
 225 Potentially novel haplotype modifier effects on the risk allele are listed by Table
 226 1.

227 Discussion

228 The current study presents results of a systematic association analysis of
 229 imputed HLA alleles with over 3,000 clinical phenotypes in more than 235,000
 230 individuals. In total, we report 3,649 statistically significant and successfully
 231 replicated allele-phenotype associations in 368 phenotypes distributed over 35
 232 disease categories. Consistently with previous HLA PheWAS and other reports
 233 (Dendrou et al., 2018), our study uncovered well-established associations with
 234 major autoimmune disorders, and also found evidence of HLA pleiotropy (Karnes
 235 et al., 2017; Liu et al., 2016) in particular between infectious and autoimmune
 236 diseases. Expectedly, the effect size estimates between the previous studies and
 237 our discovery and replication data sets showed overall high concordance,
 238 validating the accuracy of HLA imputation, phenotype data and association
 239 analyses based on these. The results from conditional analyses focusing on
 240 selected combinations of HLA alleles and cross-phenotype associations further
 241 add to the existing knowledge by including risk-modifying effects not studied
 242 before in a phenome-wide context.

Figure 4. HLA haplotype effects. Risk allele in combination with another allele of a different HLA gene. **a)** Phenotypes in which the risk allele haplotype association effects deviate from expected (i.e. sum of individual allelic effects). **b)** The x-axis shows log-odds ratios (betas) for different two-locus allele combinations depicted on the y-axis. The y-axis label indicates the primary risk allele and the tick marks indicate alleles of a different HLA gene. The vertical dashed lines indicate the risk allele's effect estimates based on allele-level analysis. Only significant (discovery FDR < 0.01, replication p < 0.01) effects on the risk allele are shown. The error bars indicate standard errors for the beta values.

In a recent well-powered association study, MHC region was linked with multiple common infectious diseases, and fine-mapping revealed several independent signals among HLA-gene variants and alleles (Tian et al., 2017). Moreover, in another study on MHC expression quantitative trait loci, protection from bacterial infections in cystic fibrosis by the common autoimmune risk haplotype AH 8.1 was found to be mediated by a non-HLA gene carried in the same haplotype (D'Antonio et al., 2019). Our finding that certain HLA alleles in common haplotypes were shared by infectious and autoimmune diseases is intriguing in regard to the proposed triggering role of infections in autoimmunity (Ercolini and Miller, 2009). The result on the *B*13:02 - DQB1*03:02* and *C*07:01 - DQB1*02:01* haplotypes showed that class I and II alleles exhibited different associated phenotypes, suggesting that these alleles may have effects that are not explained by linkage disequilibrium alone. As evidence of HLA pleiotropy was also reported by two previous MHC PheWASs (Karnes et al., 2017; Liu et al., 2016), it will be of great interest to try to reveal the mechanistic background for these shared associations, especially between infections and autoimmunity (D'Antonio et al., 2019; Matzaraki et al., 2017).

The strong enrichment of HLA risk alleles in autoimmune diseases, e.g. DQ8 in T1D, DQ2 in coeliac disease, or B27 in arthropathies, automatically leads to lower frequencies of other alleles in the risk locus and consequently to risk-reducing effect estimates irrespective of actual association. Conditional analyses adjusted for allelic variation can reveal genuine effects of the risk-gene HLA genotypes. In line with previous analyses, our HLA diplotype PheWAS replicated known protective allelic effects in e.g. in demyelinating diseases (*DRB1*07:01* and *01:01*) (Wu et al., 2010), arthropathic psoriasis (*C*07:01*) (Queiro et al., 2006), diabetes (*DQB1*06:02*) (Pugliese et al., 1995), and seropositive RA (*DRB1:13:01* and *08:01*) (van der Helm-van Mil et al., 2005) and provided estimates for risk-modifying effects of a range of alleles occurring together with the top risk allele in autoimmune disorders. Our results showed a risk-modifying effect of *DQB1*03:01* for *DQB1*05:01* in lichen planus (LP), helping resolve the somewhat contradictory results obtained by previous serotyping studies on frequencies of DQ1 and DQ3 in LP patients (Nasa et al., 1995; Porter et al., 1993).

Population founder effect can lead to reduced genetic diversity and altered frequencies of genetic variants (Chheda et al., 2017), including HLA alleles and

haplotypes (Creary et al., 2019; Hurley et al., 2020). The current study was based on genetically defined cohort of Finns that constitute a Northern European genetic isolate. A characteristic genetic architecture is visible in the repertoire of HLA haplotypes where a number of Finnish enriched rare (FER) haplotypes are substantially more common than elsewhere in Europe (Linjama et al., 2018). Our HLA class I – class II analysis demonstrates how haplotype effects can be estimated in a genetically characteristic population. We found that *B*27:05* occurring together with *DRB1*04:08* carried the highest risk for seronegative rheumatic diseases, confirming an association that has been previously described in the Finnish population (Tuokko et al., 1997). This allele combination occurs in *C*01:02 - HLA-B*27:05 - DRB1*04:08 - DQB1*03:01* haplotype that belongs to the FER group and is 3300 times more frequent in the Finnish population than in other European populations. Our study further demonstrated that the predisposing effect of *B*27:05* was effectively removed by *DRB1*04:04*. This allele pair is known to occur in the *C*01:02/02:02 - B*27:05 - DRB1*04:04 - DQB1*03:02* FER haplotype.

While HLA class I and II have been reported to be independently associated with T1D (Eike et al., 2009; Mikk et al., 2017), the compound effect of allelic heterogeneity between HLA class I and II remains less comprehensively understood. We observed protective effects for HLA class I alleles that by themselves did not have association with T1D and its comorbidities in our analyses or elsewhere in the literature (Noble and Valdes, 2011). For example, *B*27:05* and *B*40:01* occurring together with *DQB1*03:02* reduced the risk conferred by *DQB1*03:02* while *B*44:27* substantially increased it. The predisposing effect of the uncommon *B*44:27* allele in diabetes-related conditions can go unnoticed in mixed populations due its infrequency or appearance in different class II haplotypes. Allele *B*44:27* is relatively rare also in Finland and occurs mostly with *C*07:04 - B*44:27 - DRB1*16:01 - DQB1*05:02*, *DRB1*08:01 - DQB1*04:02* and *DRB1*01:01 - DQB1*05:01*. As these haplotypes lack known risk alleles, the causative variant remains unknown but suggests a potential role for *B*44:27*. Obviously, rare alleles such as *B*44:27* and haplotypes carrying it are not widely studied, and also the risk factor associated with *B*44:27* may not be the same as in *DQB1*03:02* haplotypes.

Our study is also limited in some respects. First, analysis of HLA alleles alone cannot definitively attribute the observed associations directly to HLA owing to strong linkage disequilibrium within the MHC (Trowsdale and Knight, 2013). For

example, the known associations between disorders of iron metabolism and *A*03:01*, and that between disorders of adrenal gland and *DRB1*04:04*, at least partially are a result from linkage disequilibrium with *HFE* gene and *CYP21* gene, respectively. Also, most of the rare HLA alleles were not covered by the used imputation panel and consequently the analysis did not cover their possible associations. Second, our study is restricted by statistical power particularly in conditional analyses with many covariates and in endpoints having a low number of cases. While the independent replication design of the study helps eliminate non-systematical false positives arising from e.g. relatedness, batch and other chance factors, it cannot categorically rule them out or remove sampling uncertainty in low-powered endpoints. Third, the FinnGen phenotypes, albeit carefully curated, were derived from health register which cannot be assumed to be totally accurate. Finally, haplotype analysis cannot prove that the alleles are encoded in *cis*, but the effects between two HLA genes, or chromosomal regions between them, can also take place in *trans*.

In conclusion, the results of the present study illustrate the role of HLA alleles both separately and in combination in immune-mediated diseases, revealing potentially new HLA-linked disease phenotypes and providing a data resource for future HLA analyses in independent populations. The results expand the view of the complex genetic structure of HLA, motivating the consideration of allele and gene interactions in risk calculations. These results can serve as starting points for functional studies focusing on mechanistic molecular underpinnings of the discovered associations.

Materials and Methods

Subjects and clinical endpoints

The discovery cohort of the study included all biobank participants in the FinnGen (www.finnngen.fi) data release R3 ($n_{\text{total}} = 146,630$) while the independent replication cohort comprised the data release R5 (without R3; $n_{\text{total}} = 89,340$). Numbers of cases and controls for each phenotype are given in the Supplementary Table 1. Endpoints with at least 5 cases carrying a given allele in both discovery and replication cohorts were included in the analysis. The clinical disease endpoint definitions were curated from ICD 9-10, ICD-O-3, the Social Insurance Institute (KELA) drug reimbursement codes and ATC-codes as a part of

the FinnGen project (finngen.gitbook.io/documentation/methods/endpoints). For clarity, the FinnGen phenotypes include many partially overlapping diseases or traits, particularly in diabetes and its comorbidities. Thus, the included phenotypes are not necessarily independent. All patients and control subjects provided an informed consent for biobank research in accordance with the Finnish Biobank Act, with the exception of FinnGen legacy samples which were approved by the National Supervisory Authority for Welfare and Health (Valvira). The FinnGen study protocol was approved by the Ethical Review Board of the Hospital District of Helsinki and Uusimaa (Nr HUS/990/2017). All samples and individual-level data were pseudonymized and processed in accordance with the EU GDPR law.

Genotyping

Genotyping of FinnGen samples was performed on a customized ThermoFisher Axiom array at the Thermo Fisher genotyping service facility (San Diego, USA). Genotype calling and quality control steps are described in finngen.gitbook.io/documentation/methods/genotype-imputation. The array markes files can be downloaded from www.finnngen.fi/en/researchers/genotyping. The protocol for genotype liftover to hg38/GRCh38 is described in detail in www.protocols.io/view/genotyping-chip-data-lift-over-to-reference-genome-xbhfi6?version_warning=no, and genotype imputation protocol is described in www.protocols.io/view/genotype-imputation-workflow-v3-0-xbgfijw.

HLA allele analysis

We implemented the PheWAS approach (Denny et al., 2013) for imputed alleles of *HLA-A*, *-B*, *-C*, *-DRB1*, *-DQA1*, *-DQB1* and *-DPB1* genes to analyze their correlation with 3,355 clinical case-control endpoints in 37 broad disease categories. Each analysed phenotype included at least five cases in both discovery and replication sets. HLA imputation at four-digit resolution (i.e. protein-level) was conducted as described previously (Ritari et al., 2020). Briefly, we used HIBAG v1.18.1 (Zheng et al., 2014) R library with a Finnish population-specific HLA reference panel (n = 1,150) based on ~4,500 SNPs within the MHC region (chr6:28.51-33.48 Mb; hg38/GRCh38), and considered imputation posterior probabilities > 0.5 as acceptable. For association analyses, we defined the imputed HLA alleles as bi-allelic SNPs and assumed additive effects of allele

dosages on the binary phenotype. Logistic regression models were run using SPAtest v3.0.2 (Dey et al., 2017) in R v3.6.3 (R Core Team, 2020) with top 10 genetic principal components (PCs), age and sex as covariates. To correct for multiple testing under dependency and to identify associations for validation in the replication cohort, we applied adaptive Benjamini-Hochberg (Benjamini and Hochberg, 2000; Kim and van de Wiel, 2008) procedure to the discovery cohort. SPAtest saddlepoint approximated p-values using the R library mutoss v0.1-12 (MuToss Coding Team et al., 2017) at FDR < 0.01 threshold. We considered an association valid if the replication p-value was < 0.01 and the effect direction was consistent with the discovery cohort.

To evaluate independent contributions of HLA alleles significantly associated with multiple disease categories, we performed conditional analyses that systematically included a phenotype from a different disease category as an additional covariate. In this analysis we used the whole dataset (data release R5) and genome-wide p-value threshold of 5×10^{-8} . To exclude phenotypes in strong correlation with each other from the analysis, we first computed an all-vs-all Pearson's correlation matrix between the phenotypes and removed those having a correlation >0.8 with another phenotype. Association for each HLA allele with a given phenotype was performed by including a different, non-correlating phenotype as a covariate along with age, sex and 10 genetic PCs using SPAtest as described above.

HLA diplotype analysis

To systematically study how the association effect of the primary risk allele was impacted by other alleles of the same HLA gene, we performed association analyses for HLA allele combinations (termed here as diplotypes). The top risk alleles were identified based on the lowest significant single-allele p-value for each phenotype in the discovery cohort. We performed conditional regression analyses by including all the diplotypes in the same model for a given phenotype. With this approach our aim was to quantify actual allelic effects as distinguished from nonpredisposition to the risk allele. As described above, the top 10 genetic PCs, age and sex were included as other covariates. To identify significant effects relative to the top risk genotype for a given phenotype, we performed a two-tailed Z-test on the obtained conditional logistic regression coefficients (betas) and their standard errors.

HLA haplotype analysis

The haplotype analysis was based on the observation that in some phenotypes a significant association was found both in HLA class I and class II genes. To evaluate whether alleles in a class I gene affected the risk of an allele in a class II gene, or vice versa, we considered combinations of alleles from both class I and II. The top risk allele for each phenotype was first identified based on the lowest significant single-allele p-value in the discovery cohort, and then combined with alleles of a HLA gene of a different class (termed here as haplotypes). Thus, the primary risk allele was studied in all available allele combinations of the secondary gene. HLAs were imputed on phased genotype data obtained from genotype imputation, and the combined loci under analysis were selected from the same phase. All haplotypes were included in the same regression model for a given phenotype. Two-tailed Z-test was used to evaluate the significance of the haplotypic effects.

Data availability

The FinnGen summary statistics data can be accessed through the Finnish Biobanks' FinnBB portal and the FinnGen website (https://www.finnngen.fi/en/access_results).

Code availability

The analysis code is available at https://github.com/FRCBS/HLA_PheWAS. The FinnGen genotyping and imputation protocol is described at <https://doi-org.libproxy.helsinki.fi/10.17504/protocols.io.nmndc5e>.

Acknowledgements

The study was supported by the Academy of Finland, the Finnish Cancer Association, VTR funding from the Finnish Government, and Business Finland. FinnGen funding statement is available as supplementary information. We are grateful to all FinnGen participants for their generous contribution to the project.

449 The funders and biobanks had no role in study design, data collection and
450 analysis, decision to publish, or preparation of the manuscript.
