Abstract

Background

The St. Gallen 2019 guidelines recommend omission of completion axillary lymph node dissection (cALND) in breast cancer patients with 1-2 sentinel lymph node (SLN) metastases regardless of histopathology. Concurrently, adjuvant chemotherapy is endorsed for luminal A-like disease with ≥ 4 axillary lymph node (ALN) metastases. We aimed to estimate the proportion of patients with invasive lobular cancer (ILC) and invasive ductal cancer of no special type (NST) and 1-2 SLN metastases for whom cALND would indicate need of adjuvant chemotherapy.

Methods

Patients with ILC and NST histopathology undergoing primary surgery 2014-2017 were identified in the Swedish National Quality Breast Cancer register. After exclusion of patients with incongruent or missing data, 1886 patients who fulfilled the St. Gallen 2019 criteria for cALND omission were included in the study cohort.

Results

Patients with ILC (n = 329) had a higher metastatic nodal burden and more often a luminal A-like subtype compared with NST patients (n = 1507). The prevalence of ≥ 4 ALN metastases was higher in ILC (31%) than in NST (15%), corresponding to an adjusted odds of 2.26 (95% CI 1.59-3.21). Luminal A-like breast cancers with ≥ 4 ALN metastases were overrepresented in ILC cases (52/281 (19%)) compared to NST cases (43/1299 (3%)), $P < 0.001$.

Conclusions

Patients with ILC more often had a luminal A-like breast cancer with ≥ 4 ALN metastases compared with NST patients. Abstaining cALND in patients with luminal A-like ILC with 1-2 SLN metastases warrants future attention as it risks nodal understaging and hence undertreatment in one-fifth of these patients.

Trial registration: ISRCTN registry: ISRCTN14341750

Introduction

Invasive lobular cancer (ILC) is the second most common histological subtype of breast cancer after invasive ductal cancer of no special type (NST), and comprises approximately 10-15% of all invasive breast cancer¹. ILC has distinct clinicopathological and genomic features which distinguishes it from NST, and the responsiveness to systemic treatment differs between the subtypes²⁻⁵. The majority of ILCs are classified as luminal A-like^{2, 3, 6}. Comparing patients with ILC and NST, the long-term overall prognosis seems to be the same, although a tendency towards higher incidence of late recurrences (>10 years of follow-up) has been seen in ILC^{4, 7, 8}.

ILC has a characteristic growth pattern, with single-files of tumor cells diffusely infiltrating benign tissue⁹. Both primary tumors and axillary lymph node (ALN) metastases tend to be nonpalpable and difficult to detect by diagnostic imaging, fine needle aspiration, and core needle biopsy^{5, 10-13}. The sensitivity of axillary ultrasound for detection of ALN metastases is lower in ILC compared to that for NST, especially in patients with a high metastatic nodal burden (three or more ALN metastases)¹¹. The clinical usefulness of magnetic resonance imaging of the breast and positron emission tomography and computed tomography (PET-CT) for pretreatment breast cancer staging in patients with ILC is not defined in the literature, and none of these techniques are included in current clinical practice¹⁴⁻¹⁶. Patients with ILC are thus often diagnosed at a higher stage than patients with NST, tend to have a larger proportion with ≥ 4 ALN metastases and a higher number of non-sentinel lymph node (SLN) metastases¹⁷⁻²¹. Despite these differences, current surgical and oncologic treatment guidelines are similar in patients with ILC and NST.

Presence of ALN metastases is an important negative prognostic factor in breast cancer and nodal staging is one of the cornerstones in the diagnostic work-up^{22, 23}. Until recently, the standard surgical procedure for ALN staging of clinically node negative (cN0) breast cancer has been a SLN biopsy followed by completion ALN dissection (cALND) in patients with confirmed SLN metastases. Two randomized controlled trials on ALN management, The American College of Surgical Oncology Group Z0011 trial and The International Breast Cancer Study Group 23-01 trial, have shown that, omitting cALND in patients with clinically T1-2 (≤ 5 cm) N0 and SLN positive breast cancer, did not affect the recurrence and survival rates during the first 10 years of follow-up^{24, 25}. Furthermore, another randomized controlled trial, the AMAROS trial, where patients with clinically T1-2N0 breast cancer and ≥ 1 SLN

metastases undergoing breast-conserving therapy or mastectomy were randomized to either cALND or axillary radiotherapy, showed no differences in recurrence or survival rates with 10 years of follow-up^{26, 27}. The findings from these trials have led to a change of practice in the axillary management irrespective of histological subtype.

In the guidelines from the St. Gallen 2019 consensus meeting, the expert panel included all histological subtypes in the extended indication for omission of cALND. They recommend that cALND can be omitted in clinically T3 (>5 cm) N0 breast cancer with 1-2 SLN metastases, undergoing either breast-conserving therapy or mastectomy, provided that adjuvant systemic treatment and regional nodal irradiation will be delivered⁶. In addition, these guidelines recommend that adjuvant chemotherapy should be offered to patients presenting with ≥ 4 ALN metastases and a luminal A-like tumor. Based on the limited number of ILC patients included in the above-mentioned studies (8%, 334/4192), the proposed differences in metastatic non-SLN involvement and a high incidence of recurrences more than 10 years past primary diagnosis, the applicability of criteria for omitting cALND in patients with ILC is still unclear^{28, 29}

The aims were therefore to compare the prevalence of ≥ 4 ALN metastases and the distribution of number of non-SLN metastases in ILC and NST in a large population-based cohort included in the validated Swedish National Quality Breast Cancer register³⁰ and to estimate the prevalence of luminal A-like tumors with ≥ 4 ALN metastases in ILC and NST, in patients meeting the criteria for omission of cALND according to the St. Gallen 2019 guidelines.

Methods

After study approval by the Ethics Committee (2019–02139), clinicopathological characteristics were retrieved from the Swedish National Quality Breast Cancer register for patients diagnosed with primary breast cancer. The register is a validated cancer registry with a coverage of 99.99% of all breast cancers diagnosed in Sweden³⁰. The study adheres to the STROBE guidelines for observational studies³¹. The time period 2014–2017 was chosen to ensure that key variables had a high representation and that cALND was recommended according to the Swedish Treatment Guidelines for breast cancer³² in patients with SLN metastases.

Study populations

Women diagnosed between 2014–2017 with unilateral, primary breast cancer classified as pure ILC, pure NST, or mixed ILC/NST, who underwent breast and axillary surgery as primary treatment, were identified in the Swedish National Quality Breast Cancer register ($n = 20\,139$). Patients who underwent SLN biopsy and cALND, with breast cancer eligible for omission of cALND according to the St. Gallen 2019 criteria (clinically T1-3 N0 with 1-2 SLN metastases of which at least 1 macrometastasis) were included in the main study cohort (St. Gallen 2019 cohort, $n = 1886$). In addition, a Z0011 cohort was defined as patients who underwent breast-conserving therapy and SLN biopsy, in line with the Z0011 criteria for omission of cALND (clinically T1-2 N0, 1-2 SLN metastases of which at least 1 macrometastasis), $n = 975$. Patients with node-negative disease and those with data from only SLN biopsy or ALND were excluded. The flow-chart of the study is depicted in Figure 1.

Pathological assessment and surrogate molecular subtypes

Pathological assessments of the primary tumor, SLNs and ALNs were performed in accordance with the Swedish Quality Document for Pathology³³. According to the guidelines valid at the study period, ILC was identified by specified morphological criteria and in case of a histologically uncertain specimen showing lobular growth pattern a complementary immunohistochemical staining of E-cadherin was performed. ALNs were identically prepared irrespective of histological subtype, whereas SLNs were subjected to complimentary cytokeratin staining in patients with ILC and benign hematoxylin-eosin assessment. ER and progesterone receptor (PR) positivity were defined as $\geq 10\%$ of immunohistochemically

stained nuclei, and in accordance with Prat et al., PR $\geq 20\%$ was considered high³⁴. HER2 positivity was defined as the HER2 *in situ* hybridization test positive, and if this test was missing by immunohistochemical 3+ scoring. The Ki67 percentage was categorized into 3 groups: low, intermediate and high, based on local laboratory percentile based cut-offs, and Nottingham histological grade (NHG) was evaluated according to Elston and Ellis³⁵.

In line with international guidelines, a lymph node micrometastasis was defined as a tumor deposit >0.2 mm but ≤ 2 mm consisting of ≥ 200 tumor cells, and a macrometastasis as a deposit >2 mm. Deposits ≤ 0.2 mm and/or consisting of <200 tumor cells were defined as isolated tumor cells. Patients with SLN isolated tumor cells only were classified as N0^{33, 36}. Patients with 1-2 SLN metastases with SLN micrometastases only ($n = 216$, 10%) were not included in the study cohorts (Figure 1) according to current clinical guidelines for axillary surgery, where cALND is not recommended for this group of patients^{32, 37-40}.

Based on a modification of the St. Gallen 2019 guidelines⁶ and the classification proposed by Maisonneuve et al.⁴¹ (including ER, PR, HER2, Ki67 and NHG), the surrogate molecular subtypes luminal A-like; luminal B-like; HER2 positive; and triple-negative were defined. The definitions are described in Supplementary material 1.

Statistical Analysis

The primary endpoint was prevalence of ≥ 4 ALN metastases in patients with ILC and NST, respectively. A secondary endpoint was to estimate the proportion of patients with luminal A-like tumors with ≥ 4 ALN metastases in ILC and NST, in patients meeting the criteria for omission of cALND according to the St. Gallen 2019 guidelines.

Evidence for differences in categorical variables, including patient and tumor characteristics, between the histological subtypes (ILC vs. NST) was evaluated using Pearson's chi-squared test, Fisher's exact test if one or more of the expected counts in the contingency table <5 , or Pearson's chi-squared test for trend (ordinal variables with >2 categories). Variables measured on a continuous scale were evaluated using the Mann-Whitney U-test. Uni- and multivariable analyses were performed using logistic regression.

P-values, which have not been adjusted for multiple testing, should be interpreted as level of evidence, on a continuous scale from zero to one, against the null hypothesis without reference to a cut-off for significance.

IBM SPSS Statistics (version 25.0, IBM Inc., Armonk, NY, USA) and STATA version 16 (StataCorp, College Station, TX, USA) were used for statistical calculations.

Results

Demographics and non-sentinel node metastases by histological subtype in the St. Gallen 2019 cohort

In the St. Gallen 2019 cohort, comparing 329 patients with pure ILC and 1 507 with pure NST with 1-2 metastatic SLNs, several differences in clinicopathological characteristics were identified (Table 1). Patients with ILC were older, had a lower detection rate with screening mammography and more often had mastectomy. Their tumors were larger, more often multifocal and the metastatic burden in ALNs higher. Additionally, the proportion of luminal A-like tumors was higher, while other surrogate subtypes were less frequent in ILC compared to NST. The characteristics of the mixed ILC/NST group ($n = 50$) are reported separately and the biomarker profile was closer to pure ILC than to pure NST.

The number of excised SLNs and ALNs did not differ by histological subtype (Table 1). However, one or more non-SLN metastases in the axillary specimen was more common in ILC (165/329 (50%)) than in NST (545/1507 (36%)), $P < 0.001$; odds ratio (OR) 1.78, 95% confidence interval (CI) 1.40-2.26) and the same pattern was observed in patients with ≥ 4 ALN metastases (ILC: 102/329 (31%) and NST: 224/1507 (15%)), $P < 0.001$; OR 2.57, 95% CI 1.96-3.38 (Table 1) (Figure 2a,3a). In patients with one or more non-SLN metastases, the total number of non-SLN metastases was also higher in ILC compared to NST (median (interquartile range (IQR)): 3 (1-7) vs. 2 (1-3)) (Table 1) (Figure 2b).

Four or more nodal metastases by histological and surrogate subtype in the St. Gallen 2019 cohort

Patients with luminal A-like subtype and four or more ALN metastases were overrepresented in ILC ($n = 52/281$ (19%)) compared to the NST cases ($n = 43/1299$ (3%)), $P < 0.001$; OR 6.63 95% CI 4.32-10.2) (Table 1) (Figure 3b). Moreover, the relative frequencies of ≥ 4 ALN

metastases within all the different surrogate molecular subtypes were also higher in ILC compared to NST cases in the St. Gallen cohort (Table 1, Figure 3C).

Additionally, the adjusted odds of ≥ 4 ALN metastases in patients with luminal A-like subtype were higher in ILC cases compared to NST cases (OR 2.92 (95% CI 1.73-4.94).

Multivariable analyses of axillary nodal burden in the St. Gallen 2019 cohort

The odds of one or more non-SLN metastases was higher for ILC than for NST also after adjustment for other relevant predictors including age, detection by screening mammography, T-stage, multifocality, number of SLNs with macrometastases and surrogate molecular subtypes (OR 1.55, 95% CI 1.15-2.08, $P = 0.004$) (Table 2).

Furthermore, the odds of ≥ 4 ALN metastases was higher in ILC than in NST after adjustment for the same variables as above (OR 2.26, 95% CI 1.59-3.21, $P < 0.001$) (Table 2, Figure 4). Tumor stage, multifocality, surrogate subtypes and number of SLNs with macrometastases were confirmed as predictors of ≥ 4 ALN metastases along with ILC (Table 2) (Figure 4). The luminal B-like and HER2 positive surrogate subtypes vs. luminal A-like were predictors of axillary nodal burden, whereas the low prevalent mixed ILC/NST histological subtype added no information on the risk of ≥ 4 ALN metastases (Table 2 and Figure 4).

Demographics and nodal metastatic burden in the Z0011 cohort

Clinicopathological data from the Z0011 cohort (Supplementary material 2) and the entire cohort retrieved from the register (Supplementary material 3) showed essentially the same differences between pure ILC and pure NST cases as in the St. Gallen 2019 cohort.

In the Z0011 cohort (ILC; $n = 105$, vs. NST; $n = 854$), similar distributions of patients with one or more non-SLN metastases stratified by histological subtype was noted (ILC 42% and NST 31%) $P = 0.02$; OR 1.60, 95% CI 1.06-2.43), and the proportion of patients with ≥ 4 ALN metastases was also higher in ILC (ILC 26% and NST 11%), $P < 0.001$; OR 2.90, 95% CI 1.78-4.73). Furthermore, the total number of non-SLN metastases in those with one or more non-SLNs was higher in ILC compared with NST (Supplementary material 2).

In line with the results in the St. Gallen 2019 cohort, patients in the Z0011 cohort with luminal A-like subtype and ≥ 4 ALN metastases were also overrepresented in ILC ($n = 13/83$ (16%)) compared to the NST cases ($n = 21/738$ (3%)), $P < 0.001$; OR 6.34, 95% CI 3.04-13.2) (Supplementary material 2).

In multivariable analyses predicting non-SLN metastases, ILC remained an independent predictor after adjustment (OR 1.81, 95% CI 1.11-2.98, $P = 0.018$) (Supplementary material 4). Finally, the adjusted odds of ≥ 4 ALN metastases was also higher in ILC than in NST (OR 2.94, 95% CI 1.56-5.54, $P = 0.001$) (Supplementary material 4).

Discussion

This population based Swedish registry study shows that when applying the St. Gallen 2019 guidelines for omitting cALND, the presence of non-SLN metastases and the proportion of ≥ 4 ALN metastases were higher in ILC than in NST. The present study highlights that the St. Gallen 2019 criteria for omission of cALND is associated with an understaging of ALN status, and a subsequent risk for adjuvant systemic undertreatment in the clinic, especially in ILCs with luminal A-like subtype. Most patients with NST had benign non-SLN after cALND, while in ILC, half of the patients had non-SLN involvement in the axillary specimen. Similar results were seen for the narrower but more generally accepted Z0011 criteria for abstaining cALND. Importantly, both in the St. Gallen 2019 and Z0011 cohorts, ILC was an independent predictor of non-SLN metastases and ≥ 4 ALN metastases after adjustment for validated predictors of non-sentinel node metastases. Previous studies have included a limited number of ILC and not specifically addressed residual axillary nodal involvement after abstaining cALND when applying the St. Gallen 2019 guidelines.

Breast cancer classified as luminal A-like with ≥ 4 ALN metastases was more frequent in patients with ILC compared to NST (St. Gallen 2019 cohort: $n = 52$ (19%) vs. $n = 43$ (3%), Z0011 cohort: $n = 13$, 16% vs. $n = 21$, 3%, respectively). In patients with a luminal A-like subtype, treatment recommendation on adjuvant chemotherapy depends on ALN staging according to the St. Gallen 2019 consensus guidelines even in the era of genomic testing. Although patients with the luminal B-like and HER2 positive subtypes had a higher risk of ≥ 4 ALN metastases than patients with the luminal A-like subtype, the staging information from cALND is of less importance for these patients as they would be recommended adjuvant chemotherapy irrespective of nodal status. Our results suggest that when applying the St. Gallen 2019 criteria for omitting cALND, approximately 1 out of 5 ILC and 1 out of 30 NST patients with 1-2 confirmed SLN macrometastases will not be offered adjuvant chemotherapy as a result of understaging of the axilla, and essentially the same results were seen in the Z0011 cohort. Moreover, according to Swedish Treatment Guidelines³², all patients with ≥ 4

ALN metastases would have diagnostic imaging recommended for the evaluation of metastatic disease before the start of adjuvant therapy.

Previous breast cancer studies exploring the impact of nodal staging data on adjuvant treatment decision, have not specified the histological subtypes and are based on smaller cohorts than ours^{42, 43}. Aigner et al. included 132 patients and, in line with our data, found that 17% of the patients with Z0011 eligible breast cancer would have been offered a more extensive adjuvant treatment based on the information retrieved by cALND, while Stenmark et al. included 238 patients with clinically N0 breast cancers with ≥ 1 SLN metastases (≥ 1 macrometastasis) and found that in 18% of those with luminal A-like tumors four or more ALN metastases were detected after cALND.

In the present study, including a population-based unselected cohort, patients eligible for omission of cALND according to St. Gallen 2019 and Z0011, displayed a prognostically more unfavorable ALN status, with a more extensive nodal metastatic burden, compared to those originally included in the Z0011, The International Breast Cancer Study Group 23-01 and AMAROS trials. Based on current clinical guidelines the study inclusion was restricted to those patients with 1-2 SLN metastases of which at least 1 macrometastasis, and patients with isolated tumor cells only were classified as N0, and excluded³⁶. In the seminal trials, a majority of the included patients had micrometastasis only in their SLNs and isolated tumor cells were classified as micrometastasis⁴⁴, and $\geq 90\%$ of the patients received adjuvant systemic treatment. These conditions could have affected the observed outcome data and with a follow-up time restricted to 10 years, there is still a risk for late recurrences, especially for ILC^{4, 7, 8}. Additionally, a minority of the included patients had ILC (~8%) and in none of the trials, data from subgroup analyses in ILC and NST was reported.

Studies investigating ALN status in relation to histological subtype, have shown a higher axillary metastatic burden in ILC compared to NST, but the total number of patients with ILC, strictly eligible for omission of cALND according to the Z0011 criteria and with both SLN and non-SLN data available, is low ($n = 2-24$); and complete data from those meeting the St. Gallen 2019 guidelines are for the most part either missing or not reported^{17, 19, 45-47}. While numerous prediction models have been presented to support clinical decision on cALND, only few of the models include histological or molecular subtypes⁴⁸.

This is one of the largest studies from a validated nationwide quality register exploring ALN status in ILC vs. NST in patients meeting the criteria for omission of cALND according to St. Gallen 2019 and Z0011. All tumor deposits were assessed according to current classification for isolated tumor cells, micro- and macrometastasis and prospectively performed³⁶. A weakness in this study was that no data was available on gross extracapsular extension or vascular invasion. Hence, these risk factors for ALN metastases could not be included in the multivariable analysis. Studies including registry data may be considered less reliable, given the risks of incomplete and misclassified data. In the present study, however, the original dataset was complete for histological subtype in all except 54 cases and data on nodal status was found to be incongruent or missing in 5% (1144/23 254) of the patients.

Mamtani et al. compared patients with ILC ($n = 104$) and NST ($n = 709$) treated according to Z0011 criteria, where cALND was omitted in those with 1–2 SLN metastases and performed in those with >3 SLN metastases and/or gross extracapsular extension⁴⁷. Both cases with pure ILC and mixed ILC/NST were classified as ILC. After 3.5 years of follow-up, no significant differences were seen in recurrence and survival rates when comparing all ILC and all NST cases (independent of axillary management). In the present study, the ILC/NST mixed subtype was presented separately. Although no association with the risk of a high nodal burden was found, this finding has to be interpreted with caution due to the low prevalence of the ILC/NST mixed subtype.

Whether the findings of a higher axillary nodal burden in ILC after cALND in the present study have implications on clinical outcome needs to be further investigated. A multidisciplinary discussion regarding omission of cALND is encouraged for all patients with ILC.
