31 Abstract

32 This study introduces and illustrates the potential of an integrated multi-omics approach in
 33 investigating the underlying biology of complex traits such as childhood aggressive behavior. Using
 34 multivariate statistical methods, we integrated 45 polygenic scores (PGSs) based on genome-wide
 35 SNP data, 78,772 CpGs, and 90 metabolites for 645 twins (cases=42.0%, controls=58.0%). The single-
 36 omics models selected 31 PGSs, 1614 CpGs, and 90 metabolites, and the multi-omics biomarker
 37 panel comprised 44 PGSs, 746 CpGs, and 90 metabolites. The predictive accuracy in the test ($N=277$,
 38 cases=42.2%, controls=57.8%) and validation data ($N=142$ participants from a clinical cohort,
 39 cases=45.1%, controls=54.9%) ranged from 43.0% to 57.0% for the single- and multi-omics models.
 40 The average correlations across omics layers of omics traits selected for aggression in single-omics
 41 models ranged from 0.18 to 0.28. In the multi-omics model higher correlations were found and we
 42 describe five sets of correlational patterns with high absolute correlations ($|r| \geq 0.60$) of aggression-
 43 related omics traits selected into the multi-omics model, providing novel biological insights.

44 **Keywords:** Childhood aggression; multi-omics; polygenic scores; genetic nurturing; DNA
 45 methylation; metabolomics.

46 Introduction

47 Omics studies can lead to an improved understanding of the biological mechanisms contributing
48 to mental health and disorders (Jakovljevic and Jakovljevic 2019). Different omics technologies, e.g.,
49 genomics, epigenomics, transcriptomics, or metabolomics, assess different aspects of the
50 development and progression of complex traits and disorders. The analysis of a single omics layer
51 provides a unique, but incomplete, picture of the underlying biology, whereas studies combining
52 multiple omics layers may lead to more comprehensive insights into human biology, because the
53 different omics layers are interrelated and interact (Wörheide et al. 2021). Multi-omics analyses can
54 aid in biomarker discovery, diagnosis, patient classification or subtyping, evaluation of treatment
55 response and uncovering novel insights into disease biology (Pinu et al. 2019; Subramanian et al.
56 2020).

57 Here, we present an integrative multi-omics analysis of childhood aggressive behavior. Human
58 aggression is a complex and heterogenous behavior encompassing hostile, destructive, or injurious
59 behavior aimed at causing physical or emotional harm to others (Anderson and Bushman 2002;
60 Siever 2008). In several disruptive behavioral disorders, such as conduct and oppositional defiant
61 disorders or intermittent explosive disorder, inappropriate levels of aggressive behavior are
62 observed (Radwan and Coccaro 2020). In humans, high co-occurrence with other social, behavioral,
63 and emotional problems is reported (Bartels et al. 2018; Whipp et al. 2021a). Childhood aggressive
64 behavior puts a burden on children and their parents/caretakers, and is predictive of multiple
65 adverse outcomes later in life, such as antisocial personality disorder (Whipp et al. 2019), criminal
66 convictions (Kassing et al. 2019), lower educational attainment (Vuoksima et al. 2020), or negative
67 interpersonal relationships (Fergusson et al. 2005).

68 Large-scale genome-wide association (GWA) studies on aggression have not yet identified
69 significant single nucleotide polymorphisms (SNPs) (Odintsova et al. 2019; Ip et al. 2021). Gene-
70 based analysis for childhood aggression yielded three significantly associated genes (*ST3GAL3*,

71 *PCDH7*, and *IPO13*) (Ip et al. 2021). The polygenic score for childhood aggression does not only
 72 significantly explain childhood aggressive behavior at age 7 (Ip et al. 2021), but it also associated
 73 with aggression at age 12 to 41 in a Dutch sample and age 38 to 48 in an Australian sample (van der
 74 Laan et al. 2021). Small-scale epigenetic studies (sample size range: 41-260) showed that DNA
 75 methylation differences in various tissues associated with aggression and related traits in children
 76 and adults (Guillemin et al. 2014; Cecil et al. 2018b, a; Mitjans et al. 2019). The first large-scale
 77 epigenome-wide association analyses (EWAS) meta-analysis across child and adult cohorts (N =
 78 15,324) reported 13 significant sites in peripheral blood for broad aggression across the lifespan (van
 79 Dongen et al. 2021). Metabolomics studies (sample size range: 77-725) detected plasma and serum
 80 metabolites associated with aggression and related traits in adults (Gulsun et al. 2016; Chen et al.
 81 2020; Whipp et al. 2021b). And a study in 1,347 twins and 183 clinical cases found significant
 82 associations of urinary metabolites with childhood aggression (Hagenbeek et al. 2020). These single
 83 omics approaches hint at potentially important biological pathways for human aggression, with most
 84 of these findings awaiting replication.

85 In this study, we aim to integrate multiple omics layers to construct a multi-omics biomarker
 86 panel for childhood aggressive behavior and explore the correlations among the omics traits
 87 included in this panel. We collected biological samples in a subproject of ACTION (Aggression in
 88 Children: Unraveling gene-environment interplay to inform Treatment and InterventiON strategies):
 89 the ACTION Biomarker Study (Boomsma 2015; Bartels et al. 2018; Hagenbeek et al. 2020). The
 90 ACTION Biomarker Study comprised a cohort of twins from the Netherlands Twin Register (NTR)
 91 (Ligthart et al. 2019) and a clinical cohort of children referred to a youth psychiatry clinic (LUMC-
 92 Curium, the Netherlands). The genome-wide SNP and DNA methylation (Illumina EPIC 850K array)
 93 data, and the urinary amines and organic acids as measured in these cohorts were previously
 94 included in a genome-wide genetic and epigenetic association study and a metabolomics study of
 95 (childhood) aggression (Hagenbeek et al. 2020; van Dongen et al. 2021; Ip et al. 2021). We expand
 96 on these single-omics studies, by integrating this data with a third metabolomics dataset, focusing

on urinary steroid hormones, and calculating transmitted and non-transmitted polygenic scores (PGSs) for childhood aggression and a series of genetically correlated traits, such as Attention-Deficit Hyperactivity Disorder (ADHD), smoking, and intelligence. The non-transmitted PGSs assess the indirect effects of genetic variants that were not transmitted from parents to offspring, i.e., genetic nurture, and capture the effects of the environment created by parents beyond the genetic intergeneration transmission (Kong et al. 2018). Thus, if alleles not transmitted from parents to offspring affect offspring outcomes, this indicates that the offspring's home-environment is influenced by parental genotypes, and the home-environment in turn affects offspring outcomes (Branje et al. 2020).

We employed an analytical design comprising three phases: 1) single-omics analyses; 2) pairwise cross-omics analyses; and 3) multi-omics analyses (Fig. 1) (Duruflé et al. 2020). First, we built single-omics biomarker panels in the twin cohort, with 70% of the twin data for model training, 30% of the twin data for model testing, and the clinical cohort for model validation. Second, we examined the overall pairwise cross-omics correlations and the pairwise correlations of those omics traits selected by the single-omics models in the training data. Third, using the same data split for model training, testing and validation, we compared three multi-omics models, with different assumptions on the correlations among the omics traits and describe the multi-omics correlations of the selected omics traits.

Materials and methods

Study population and procedures

Participants included 1,494 twins (747 complete pairs) from the Netherlands Twin Register (Ligthart et al. 2019), and 189 children referred to the LUMC-Curium youth psychiatry clinic in the Netherlands that took part in the ACTION Biomarker Study (Aggression in Children: Unraveling gene-environment interplay to inform Treatment and InterventiON strategies) (Boomsma 2015; Bartels et al. 2018; Hagenbeek et al. 2020). Both cohorts collected first-morning urine samples and buccal-cell

swabs with standardized protocols (for details, see **Appendix A**). In the twin cohort, we also collected buccal-cell swabs from parents and siblings of the twins. The current study included participants if they had aggression status, complete omics data for all three omics layers, and all relevant covariates (**Table S1**). Parents provided written informed consent for their children and twin parents provided written informed consent for their own participation. Study approval was obtained from the Central Ethics Committee on Research Involving Human Subjects of the VU University Medical Center, Amsterdam (NTR 25th of May 2007 and ACTION 2013/41 and 2014.252), an Institutional Review Board certified by the U.S. Office of Human Research Protections (IRB number IRB00002991 under Federal-wide Assurance- FWA00017598; IRB/institute codes), and the Medical Ethical Committee of Leiden University Medical Center (B17.031, B17.032 and B17.040).

Aggressive behavior

Mothers and teachers rated aggressive behavior on the Aggressive Behavior syndrome scale of the Achenbach System of Empirically Based Assessment (ASEBA) Child Behavior Checklist (CBCL) or Teacher Report Form (TRF) (Achenbach et al. 2017). We have described selection and definition of aggression cases and controls previously (Hagenbeek et al. 2020). In brief, we selected twin pairs based on concordance (case-case or control-control) and discordance (case-control pairs) for mother- (93%) or teacher-rated (7%) aggressive behavior at ages 3, 7, and/or 10 years. We matched concordant control pairs on postal code to the case-case and case-control pairs, and collection of biological samples within regions in the Netherlands was around the same time. Cases were defined by mother- or teacher-rated sex- and age-specific T-scores of 65 or higher (subclinical levels), or on mother-rated age-specific thresholds on the item scores at age 3 (≥ 13), age 7 (≥ 5), or age 10 (≥ 4) ($N = 388$, **Table S1**). We denoted individuals with scores below these thresholds as controls ($N = 534$, **Table S1**). In the clinical cohort, children with a parent-rated sex-specific T-score of ≥ 70 (clinical levels) were classified as cases ($N = 64$), and children with T-scores of < 65 were classified as low scoring controls ($N = 78$, **Table S1**). We excluded children with T-scores in the subclinical range (T-scores of ≥ 65 and < 70) from this study ($N = 35$).

Omics measurements

Details on omics measurements are included in **Appendix B**. Genotyping was performed on Affymetrix Axiom or Illumina GSA arrays (Ehli et al. 2017; Beck et al. 2019), and genome-wide SNP data were available for 3,334 participants, including 1,702 parents and siblings of twins (AXIOM = 909, GSA = 2,425). Transmitted and non-transmitted polygenetic scores (PGS) were calculated for childhood aggression and 14 other traits that showed a significant ($p < 0.02$) genetic correlation of ≤ -0.40 or ≥ 0.40 with childhood aggression (Ip et al. 2021) (**Table 1**). Thus, in total we calculated 45 PGSs: a transmitted (15), non-transmitted by mother (15), and non-transmitted by father (15) PGS for each trait. The effects of sex, age at biological sample collection, genotyping platform, and the first 10 genetic principal components (PCs) were regressed on the standardized PGSs and we included residuals in the analyses.

Genome-wide DNA methylation was measured on the Infinium MethylationEPIC BeadChip Kit (Illumina, San Diego, CA, USA (Moran et al. 2016)). Quality Control (QC) and normalization were carried out with pipelines developed by the Biobank-based Integrative Omics Study (BIOS) consortium (Sinke et al.). From the 787,711 autosomal methylation probes that survived QC, the top 10% most variable probes were included in the analyses (**Data S1**). Residual methylation levels were obtained by regressing the effects of sex, age, percentages of epithelial and natural killer cells, EPIC array row, and bisulfite sample plate, from the methylation β -values.

Urinary metabolomics data were generated on: 1) a liquid chromatography mass spectrometry (LC-MS) platform targeting amines; 2) a LC-MS platform targeting steroid hormones; and 3) a gas chromatography (GC) MS platform targeting organic acids. We excluded metabolites with a relative standard deviation of the QC samples larger than 15% and retain 60 amines, 10 steroids, and 20 organic acids in our analyses. After QC, we normalized metabolite levels to the sample-median and inverse normal rank transformed. We analyzed residuals obtained by regressing the effects of sex and age on the normalized and transformed urinary metabolites.

Statistical analyses

To define multi-omics biomarker panels capable of discriminating between cases and controls and explore the correlations among the omics traits included in these panels, we employed an analytical design comprising three phases: 1) single-omics analyses; 2) pairwise cross-omics analyses; and 3) multi-omics analyses (**Fig. 1**). To avoid overfitting of the single- and multi-omics models, we randomly split the twin sample at the twin pair level into two subsets: 70% of the data for model training (training data), and 30% of the data for model testing (test data; **Table 2**). The clinical validity of the final single- and multi-omics models was evaluated in the clinical cohort (validation data; **Table 2**). We carried analyses out in the mixOmics R package (version 6.12.1) implemented in the R programming language (version 4.0.2) (R Core Team; Rohart et al. 2017).

Phase 1: Single-omics analyses

Univariate polygenic score analyses

In the training data, we first associated the transmitted- and non-transmitted PGSs with childhood aggression through generalized estimating equation (GEE) models. GEE models tested the association of each transmitted and non-transmitted PGS separately on the continuous mother-rated sum scores of the ASEBA CBCL Aggressive Behavior syndrome scale as assessed at the time of biological sample collection. All models included sex, age, genotype array, and the first 10 genetic principal components as covariates. We corrected for the correlation structure within families by using the “exchangeable” correlation structure, obtaining robust variance estimators (Rogers and Stoner 2016). A False Discovery Rate (FDR) of 5% for 45 PGSs was used to correct for multiple testing (p.adjust function in R), setting the significance threshold to $q \leq 0.05$, i.e., 5% of the significant results will be false positives (Benjamini and Hochberg 1995).

Multivariate single-omics models

To get a first insight into the dimensionality of the metabolomics data (90 variables), DNA methylation data (78,772 variables), and the PGSs (45 variables), we ran Principal Component

Analysis (PCA) within each omics layer in the training data (**Table S2**). To assess the ability of each of the three omics layers to correctly classify aggression status, we applied Partial Least Square Discriminant Analysis (PLS-DA) in the training data. PLS-DA involves iteratively constructing successive latent components, where each component is a linear combination of the included omics traits (Rohart et al. 2017). For each component, PLS-DA aims to maximize the covariance between the residual X matrix, containing the omics data, and the Y matrix, containing the sample classification (i.e., case-control status coded as a dummy variable). The mixOmics software requires a user-defined maximum number of components in PLS-DA models. We chose this maximum based on the number of PCs as determined by the elbow method in the PCA (**Fig. S1; Table S2**). To find the optimal number of components to keep in each PLS-DA model, we employed 10-fold cross-validation (CV) with 100 repeats (*perf* function; **Table S3; Fig. S2**).

Next, we applied sparse PLS-DA (sPLS-DA) to reduce the number of traits in each omics layer contributing to each component. sPLS-DA includes Least Absolute Shrinkage and Selection Operator (LASSO) penalization (e.g., *L1* penalization). LASSO shrinks the coefficients of less importance, often highly correlated, traits to zero, removing these traits from the model (Tibshirani 1996). Thus, for each component, sPLS-DA finds the maximum covariance between the residual X matrix containing a subset of the omics data with non-zero coefficients (variable selection) and the Y matrix (Lê Cao et al. 2011). We assessed the trait selection via 10-fold CV with 100 repeats (*tune* function), keeping at least two components in the final model (**Table S3; Fig. S3**). CV again obtained the performance of the final sPLS-DA model using the *perf* function (10 folds, 100 repeats; **Table S3; Fig. S4**).

The ability of the final single-omics models to accurately predict out-of-sample case-control status was evaluated in the test and validation data (*predict* function). For each new observation in the test and validation data, this function calculates the predicted class (case/control) by estimating their predicted dummy variable (of the case-control status) using the maximum, Mahalanobis, or Centroids (Euclidian) distance (see Rohart et al. 2017). When using the maximum distance, the

predicted class of a new observation is the class for which we observed the largest predicted dummy value. Both the Mahalanobis and centroids distances are centroid-based distances that predict the class of a new observation, so that the distance between its centroid and predicted scores is minimal. To out-of-sample case-control status, we used the best performing prediction distance, as was determined during model training (see **Table S3**).

The misclassification rates of the models, that combine the number of cases classified as controls (false negative rate) and the number of controls classified as cases (false positive rate), was used to evaluate how well the final models predicted case-control status. We employed a balanced misclassification rate, the balanced error rate (BER), that corrects for imbalances in the number of cases and controls. We used a confusion matrix, comparing the true cases and controls with the predicted cases and controls, to calculate the sensitivity (number of cases correctly classified as cases [true positive rate]), specificity (number of controls correctly classified as controls [true negative rate]), and accuracy (overall correct classification). As an alternative, Receiver Operating Characteristic (ROC) analysis assessed the Area Under the Curve (AUC) in both the test and validation data. We obtained the ROC curve per component.

Phase 2: Pairwise cross-omics analyses

To highlight pairwise cross-omics relationships (i.e., DNA methylation-metabolomics, PGSS-metabolomics, and PGSS-DNA methylation), Partial Least Squares (PLS) regression models were constructed in canonical mode in the training data. Similar to canonical correlation analysis, canonical PLS regression aims to find linear combinations of the variables (canonical variates) to reduce the dimensionality of the data while maximizing the covariance between the variates (Rohart et al. 2017). CV has not yet been implemented for PLS in canonical mode. Consequently, we kept the smallest number of components as kept in either of the respective single-omics models (**Table S3**). Therefore, we included 3 components for the DNA methylation-metabolomics model, and 2 components for the PGS-metabolomics and PGS-DNA methylation models.

The PLS models were run with two different numbers of included omics traits, 1) a PLS model that included all 45 PGs, 78,772 CpGs, and 90 metabolites (model 1), and 2) a PLS model that only included the 36 PGs, 1,614 CpGs, and 90 metabolites that were selected by the single-omics sPLS-DA models (model 2; **Data S2**). Model 1 provides insight into the correlations among all omics traits, while model 2 provides insight into the correlations of those omics traits that best contribute to aggression case-control classification in the single-omics sPLS-DA models. On the omics traits included in model 2, we performed hierarchical clustering with the Ward linkage algorithm on Euclidean distances of the PLS variates and used the ‘dendextend’ R-package (Galili 2015) to extract the two largest clusters for both of the omics layers included in the PLS models.

Phase 3: Multi-omics analyses

The multi-omics analysis was conducted through Data Integration Analysis for Biomarker discovery using Latent cOmponents (DIABLO) in the training data. DIABLO extends PLS-DA to multi-block PLS-DA (MB-PLS-DA), that aims at identifying correlated traits from multiple omics layers that maximize the sample classification (Singh et al. 2019). The method requires a user-defined ‘design matrix’, that specifies the expected correlations among the omics layers. The symmetric design matrix has the number of rows and columns equal to the number of omics layers (i.e., 3), and contains values between 0 and 1. A ‘full’ design matrix denotes strong positive correlations among the omics layers and sets the values among omics layers close to or equal to one. A ‘null’ design matrix denotes weak or no correlations among omics layers by setting values close to or equal to zero. The full design matrix optimizes correlations among the omics layers, while the null design matrix optimizes the discrimination between samples (Rohart et al. 2017; Singh et al. 2019; Duruflé et al. 2020). We can also specify a design matrix with the empirical correlations among the omics layers.

We compared a multi-omics model with an empirical design matrix (based on the correlations obtained from the model 1 pairwise cross-omics PLS models; **Table S4**) to models with a null or full

design matrix. Based on the results of the single-omics sPLS-DA models (**Table S5**), we chose the maximum number of components to include in the MB-PLS-DA models. We determined the optimal number of components to keep in the MB-PLS-DA model with 10-fold CV and 100 repeats (*perf* function; **Fig. S5**). We assessed the trait selection per component per omics layer via 5-fold CV with 50 repeats (*tune* function; **Table S5**; **Fig. S6**). Performance of the final MB-sPLS-DA model was assessed with 5-fold CV (50 repeats; **Table S5**; **Fig. S7**).

The ability of the final multi-omics models to predict out-of-sample case-control status was evaluated in the test and validation data (*predict* function), using the best performing prediction distance as was determined during model training (see **Table S5**). The final multi-omics models were evaluated by their balanced error rates, and the sensitivity, specificity, and accuracy of the models were calculated from their confusion matrices. In the multi-omics models, we calculated the ROC curves per component for each omics layer.

Biological characterization

To facilitate biological interpretation, we describe the correlations of the PGSs, CpGs, and metabolites, that were selected by the single-omics sPLS-DA models and those selected by the multi-omics MB-sPLS-DA models. For the multi-omics MB-sPLS-DA models we also identified correlation patterns that included high absolute correlations ($|r| \geq 0.60$) between omics traits of at least two omics layers. To test for enrichment of methylation sites previously associated with other traits, we performed trait enrichment analysis for all traits (619) in the EWAS atlas on the 18th of June 2021 (Li et al. 2019). CpGs served as input for the trait enrichment analysis if 20 or more unique CpGs were selected into the single-omics sPLS-DA model, the multi-omics MB-sPLS-DA models, or included in a multi-omics MB-sPLS-DA high correlation pattern. When fewer than 20 CpGs were selected, we manually retrieved the trait associations with the CpGs from the EWAS atlas. Similarly, we performed trait enrichment analysis or manual retrieval of the CpGs included in the clusters as

identified for the pairwise cross-omics analyses for all traits (618) in the EWAS atlas on the 1st of July 2021.

Results

Polygenic prediction

Transmitted and non-transmitted PGSs for childhood aggression and 13 other traits were individually not significantly associated with aggressive behavior after multiple testing correction (**Data S3**). The transmitted PGS for ADHD were significantly associated with aggressive behavior ($\beta = 1.16$, $SE = 0.26$, $q = 0.0003$), while the non-transmitted PGSs were not (mother: $\beta = -0.22$, $SE = 0.24$, $q = 0.83$; father: $\beta = 0.02$, $SE = 0.23$, $q = 0.98$), showing that genetic liability for ADHD associates with increased levels of aggressive behavior.

Single-omics models for childhood aggression

We built single-omics biomarker panels for childhood aggressive behavior based on sPLS-DA models including PGSs, DNA methylation, or metabolomics data. After extensive cross-validation the optimal models included 11 transmitted and 25 non-transmitted PGSs (2-component model), across all components, 1,614 CpGs (6-component model), and all 90 metabolites (2-component model) (**Table S3; Data S2**). All three single-omics models showed poor separation of aggression cases and controls on all components (**Fig. S8**). Prediction in the test data showed that model performance was at most slightly better than random assignment of case-control status for the PGSs (BER = 0.51-0.51, range is for the different components), for the DNA methylation data (BER = 0.44-0.51), and for the metabolomics data (BER = 0.52-0.54; **Table S6**). In the validation data, the average classification accuracy was better for the metabolomics model (BER = 0.48-0.51), but not for the PGS (BER = 0.50-0.51) and DNA methylation models (BER = 0.48-0.58; **Table S6**). Similarly, the single-omics models had low sensitivity and specificity in both the test and validation data and ROC curve analyses showed the AUCs ranged from 0.48 to 0.58 in the test data and from 0.39 to 0.58 in the validation

data (**Table S6**). As a result, we observed a low degree of separation among cases and controls in both the test and validation data (**Fig. S9-S10**).

Out of the 36 selected PGSs, 11 transmitted and 16 non-transmitted PGSs (75%) were selected with high stability, i.e., included in 80% of the cross-validation rounds (**Data S2**). PGSs that were consistently included in the sPLS-DA model for childhood aggression, included the transmitted and both non-transmitted PGSs for childhood aggression and number of cigarettes per day, the transmitted and non-transmitted by mother PGSs for ADHD, age at first birth, Major Depressive Disorder (MDD), insomnia, loneliness, and Educational Attainment (EA), the transmitted and non-transmitted by father PGSs for smoking initiation, both non-transmitted PGSs for self-reported health, the transmitted PGSs for wellbeing spectrum and age of smoking initiation, the non-transmitted by mother PGSs for Autism Spectrum Disorder (ASD) and intelligence, and the non-transmitted by father PGS for childhood IQ. The remaining PGSs included in the final sPLS-DA model had a stability ranging from 50%-78%, and included the non-transmitted by mother (childhood IQ, wellbeing spectrum, age at smoking initiation, and smoking initiation) and non-transmitted by father scores (intelligence, MDD, ADHD, wellbeing spectrum, and ASD).

In contrast, only 56 out of the 1,614 CpGs (3.5%) were selected with high stability (range = 0.1%-97.9%; **Data S2**). We performed trait enrichment analyses against all reported associations in the EWAS atlas for all selected CpGs in the sPLS-DA model. We observed the strongest enrichment for glucocorticoid exposure (i.e., administration of corticosteroid medication (Braun et al. 2019); OR = 18.02, $p = 5.34 \times 10^{-158}$), and household socioeconomic status in childhood (OR = 9.88, $p = 1.18 \times 10^{-13}$; **Table S7**). In addition, we saw enrichment for many other traits, not obviously related to aggressive behavior. All 90 metabolites selected by the sPLS-DA model were selected with high stability (**Data S2**).

Pairwise cross-omics models

The average correlations between each omics layer from pairwise PLS cross-omics models including all omics traits, i.e., the correlation among all PLS variates of all components simultaneously, were $r = 0.18$ ($q = 3.19 \times 10^{-15}$) for DNA methylation-metabolomics, $r = 0.28$ ($q = 7.97 \times 10^{-24}$) for PGSS-metabolomics, and $r = 0.29$ ($q = 2.30 \times 10^{-26}$) for PGSS-DNA methylation (**Table S4**). We observed a decrease in the average correlations between the PGSSs and CpGs ($r = 0.28$, $q = 9.57 \times 10^{-24}$), but not between the PGSSs and metabolites or the CpGs and metabolites, when including only the omics traits selected through single-omics sPLS-DA in the pairwise PLS cross-omics models (**Table S4**). Overall, these correlations suggest that omics traits for childhood aggression from different omics layers capture largely independent information and that childhood aggression is associated with variation across different omics layers.

Pairwise DNA methylation-metabolomics correlations

In the pairwise DNA methylation-metabolomics model, we used hierarchical clustering and found two clusters of CpGs and of metabolites (**Fig. 2a**; **Data S4**). The DNA methylation cluster 1 contains 1,151 (71.3%) of the CpGs selected by the sPLS-DA models for childhood aggression. These CpGs located across the genome, have the largest number of CpGs on chromosome 1 ($N = 112$, 9.7%), and chromosome 2 ($N = 93$, 8.1%), and the strongest trait enrichments for these CpGs were observed for household socioeconomic status in childhood ($OR = 12.48$, $p = 4.20 \times 10^{-14}$), and psoriasis ($OR = 3.70$, $p = 1.18 \times 10^{-10}$; **Table S8**). The 463 (28.7%) CpGs included in cluster 2 are also located across the genome, with chromosome 3 ($N = 43$, 9.3%), and chromosome 4 ($N = 39$, 8.4%) containing the largest amount of cluster 2 CpGs, that show the strongest trait enrichment for glucocorticoid exposure ($OR = 51.25$, $p \leq 1.00 \times 10^{-308}$; **Table S8**). Metabolite cluster 1 contains 69 (76.7%) of the metabolites, including 55 amines, 7 organic acids and 7 steroids, while metabolite cluster 2 contains 21 metabolites (23.3%), including 5 amines, 13 organic acids, and 3 steroids.

The correlation of the CpGs included in cluster 1 with metabolites ranges from -0.20 to 0.19 (r M = -0.001, r SD = 0.02; **Fig. 2a; Data S4-S5**). The correlations of the cluster 1 CpGs with the cluster 1 metabolites are lower (r M = -0.005, r SD = 0.02, r range = -0.19-0.19) than those observed with the cluster 2 metabolites (r M = 0.01, r SD = 0.01 r range = -0.20-0.19). The CpGs included in cluster 2 have correlations ranging from -0.23 to 0.18 with metabolites (r M = -0.05, r SD = 0.01), with predominantly negative correlations observed between these CpGs and the amines included in metabolite cluster 1 (r M = -0.095, r SD = 0.01, r range = -0.23-0.18; **Fig. 2a; Data S4-S5**). We observed the highest absolute correlations ($|r| \geq 0.20$) between metabolites of cluster 1 and CpGs included in cluster 2, specifically, the amines 3-methoxytyramine (r M = -0.21, r SD = 0.01, r range: -0.23 to 0.20), asymmetric dimethylarginine (ADMA, r M = -0.20, r SD = 0.002, r range: -0.21 to -0.20), L-glutamic acid (r = -0.20), L-phenylalanine (r M = -0.20, r SD = 0.003, r range: -0.21 to -0.20), O-acetyl-L-serine (r = -0.20), and symmetric dimethylarginine (SDMA, r M = -0.21, r SD = 0.004, r range: -0.22 to -0.20) show negative correlations with these CpGs (**Fig. 2a; Data S4-S5**), showing that increased levels of these urinary metabolites associated with hypomethylation at cluster 2 CpG sites.

Pairwise PGSs-metabolomics correlations

Hierarchical cluster of the pairwise PGSs-metabolomics model identified two clusters of PGSs and two clusters of metabolites (**Fig. 2b; Table S9**). The PGS cluster 1 contains 23 of the PGSs (63.9%) selected by the sPLS-DA model for childhood aggression (**Fig. 2b; Table S9**). This cluster contains 8 transmitted PGSs, 9 PGSs non-transmitted by mother and 6 non-transmitted by father, including the transmitted and both non-transmitted PGSs for ADHD, childhood aggression, number of cigarettes per day, and MDD, the transmitted and non-transmitted by mother PGSs for insomnia, both non-transmitted PGSs for smoking initiation and ASD, the transmitted PGSs for age at first birth, EA, and wellbeing spectrum, and the non-transmitted by mother PGSs for age at smoking initiation and loneliness. The 13 PGSs (36.1%) included in cluster 2 include 3 transmitted PGSs, 6 PGSs non-transmitted by mother, and 4 by father (**Fig. 2b; Table S9**). This cluster encompasses the transmitted PGSs for age of smoking initiation, loneliness, and smoking initiation, both the non-transmitted PGSs

for childhood IQ, intelligence, self-reported health, and wellbeing spectrum, and the non-transmitted by mother PGSs of age at first birth and EA. We observed that the PGSs for wellbeing spectrum, smoking initiation, age at first birth, and age at smoking initiation are not assigned to the same cluster, but included across clusters 1 and 2 (**Fig. 2b; Table S9**). For these four traits, we observed a high number of opposite directions in the correlations among the metabolites and the transmitted and non-transmitted PGSs, i.e., 66.7%, 100%, 76.7%, and 62.2%, respectively (**Fig. 2b; Data S6; Table S10**).

The metabolite cluster 1 contains 46 metabolites (51.1%), all amines (76.7% of all amines) (**Fig. 2b; Table S9**). The remaining 14 amines, as well as all steroids and organic acids, are included in metabolite cluster 2 ($N = 44$, 48.9%, **Fig. 2b; Table S9**). Despite these differences, these clusters are still similar to those observed in the DNA methylation-metabolomics model, with 46 (66.7%) and 21 (47.7%) overlapping metabolites included in cluster 1 and 2, respectively.

Overall, we observed correlations ranging from -0.18 to 0.26 for the PGSs in cluster 1 with metabolites ($r_M = 0.015$, $r_{SD} = 0.02$), and from -0.24 to 0.19 for the cluster 2 PGSs with metabolites ($r_M = -0.03$, $r_{SD} = 0.02$; **Fig. 2b; Data S6; Table S9**). We observed the highest positive correlations ($r \geq 0.20$) between the non-transmitted by father ADHD (ADHD_NTf) and smoking initiation PGSs (smokinginitiation_NTf) with both essential and non-essential amino acids, such as L-leucine or L-alanine (ADHD_NTf $r_M = 0.21$, $r_{SD} = 0.01$, r range: 0.21-0.22, smokinginitiation_NTf $r_M = 0.22$, $r_{SD} = 0.02$, r range: 0.20-0.26). Similarly, the most negative correlations ($r \leq -0.20$) were observed between amino acids and the non-transmitted by father PGSs for intelligence (intelligence_NTf) and self-reported health (selfreportedhealth_NTf, intelligence_NTf $r_M = -0.21$, $r_{SD} = 0.01$, r range: -0.22 to -0.21, selfreportedhealth_NTf $r_M = -0.21$, $r_{SD} = 0.01$, r range: -0.22 to -0.20). This shows that characteristics tagged by ADHD, smoking initiation, intelligence, and self-reported health correlated to parental construction of environments influencing offspring urinary amino acid levels.

Pairwise PGSs-DNA methylation correlations

For the pairwise PGSs-DNA methylation model, we again applied hierarchical clustering to find two clusters for the PGSs and DNA methylation data (**Fig. 2c; Data S7**). PGS cluster 1 contains 22 of the PGSs (61.1%) selected by the sPLS-DA model for childhood aggression (**Fig. 2c; Data S7**). This cluster contains 6 transmitted PGSs, 9 PGSs non-transmitted by mother and 7 non-transmitted by father, including the transmitted and both non-transmitted PGSs for ADHD, and MDD, the transmitted and the non-transmitted by mother PGSs for smoking initiation, and wellbeing spectrum, both the non-transmitted PGSs for aggression, and number of cigarettes per day, the transmitted PGSs for age at first birth, and EA, the non-transmitted by mother PGSs for age of smoking initiation, insomnia, and loneliness, and the non-transmitted by father PGSs for ASD, childhood IQ, and intelligence. The 14 PGSs (38.9%) included in cluster 2 include 5 transmitted PGSs, 6 PGSs non-transmitted by mother, and 3 by father. This cluster encompasses both the non-transmitted PGSs for self-reported health, the transmitted PGSs for age smoking initiation, aggression, number of cigarettes per day, insomnia, and loneliness, the non-transmitted by mother PGSs for age at first birth, ASD, childhood IQ, EA, and intelligence, and the non-transmitted by father PGSs for smoking initiation, and wellbeing spectrum. The clusters as identified in this model are highly similar to those observed in the PGSs-metabolomics model, with 16 (69.6%) and 9 (69.2%) overlapping PGSs included in cluster 1 and 2, respectively (**Table S9; Data S7**). Although the PGSs-metabolomics and PGSs-DNA methylation models produce very similar clusters for the PGSs, we observe that only the PGSs for self-reported health, ADHD, and MDD were assigned to the same cluster, while the PGSs of only four traits had not been assigned the same cluster in the PGSs-metabolomics model (**Table S9; Data S7**).

The DNA methylation cluster 1 contains 1,142 (70.8%) of the CpGs selected by the sPLS-DA models for childhood aggression, and shows the strongest trait enrichments for household socioeconomic status in childhood ($OR = 12.58$, $p = 3.68 \times 10^{-14}$), and psoriasis ($OR = 3.73$, $p = 9.55 \times 10^{-11}$; **Table S11**). The 472 (29.2%) CpGs included in cluster 2 show the strongest trait enrichment for

glucocorticoid exposure ($OR = 50.00$, $p \leq 1.00 \times 10^{-308}$; **Table S11**). The clusters as identified in this model are nearly identical to those observed in the DNA methylation-metabolomics model, with 1,142 (99.2%) and 463 (98.1%) overlapping CpGs included in cluster 1 and 2, respectively (**Data S4**; **Data S7**).

The correlations of PGSs in cluster 1 and 2 with the CpGs ranged from -0.10 to 0.15 ($r_M = 0.02$, $r_{SD} = 0.02$) and from -0.19 to 0.11 ($r_M = -0.03$, $r_{SD} = 0.02$), respectively, and the correlations of the CpGs in cluster 1 and 2 with the PGSs ranged from -0.15 to 0.13 ($r_M = 0.0002$, $r_{SD} = 0.01$) and from -0.19 to 0.15 ($r_M = -0.005$, $r_{SD} = 0.004$), respectively (**Fig. 2c**; **Data S7-S8**). We observed a high number of near zero correlations among the PGSs and CpGs, that likely contribute to the high number of opposite direction correlations among the CpGs and the transmitted and non-transmitted PGSs ($N_M = 906$, $N_{SD} = 499$, $N_{range} = 38-1614$; **Fig. 2c**; **Data S8**; **Table S12**). The most negative correlations ($r \leq -0.15$) were observed between the non-transmitted by father self-reported health PGS with CpGs of cluster 2 ($r_M = -0.18$, $r_{SD} = 0.01$, $r_{range} = -0.19$ to -0.15), and the highest positive correlations ($r \geq 0.15$) between the cluster 2 CpGs and the non-transmitted by father ASD PGS ($r_M = 0.151$, $r_{SD} = 0.001$, $r_{range} = 0.150-0.154$; **Fig. 2c**; **Data S8**). This shows that characteristics tagged by ASD and self-reported health correlated to paternal construction of environments influencing offspring buccal DNA methylation levels.

Multi-omics model for childhood aggression

We built multi-omics panels for childhood aggressive behavior based on multi-block sPLS-DA (MB-sPLS-DA) models, including PGSs, DNA methylation, and metabolomics data. Here, we report the multi-omics model with an empirical design matrix and results for the null and full design matrices can be found in **Appendices C** and **D**, respectively. After cross-validation, the optimal 5-component model included 14 transmitted and 30 non-transmitted PGSs, 746 CpGs, and all 90 metabolites, across all components (**Table S5**; **Data S9**). The multi-omics model showed poor separation of aggression cases and controls both across omics blocks and within omics blocks (**Fig.**

S11). Multi-omics prediction of aggression case-control status in the test data showed an improvement in the prediction (BER = 0.47-0.52; **Table S13**) as compared to single-omics models including only the PGSs or metabolomics data, but not as compared to the model including only the DNA methylation data (**Table S6**). In contrast, in the clinical cohort, the average classification accuracy was poorer in the multi-omics model (BER = 0.53-0.57; **Table S13**) than for the single-omics models (**Table S6**). While the sensitivity and specificity of the multi-omics model was low, ROC curve analyses showed the AUCs ranged from 0.63 to 0.76 in the test data and the clinical cohort (**Table S13**), which is an improvement in comparison to the single-omics models (**Table S6**). As for the single-omics models, we observed a low degree of separation among cases and controls in both the test data and in the clinical cohort for the multi-omics model (**Fig. S12-S13**).

The multi-omics model selected all 30 non-transmitted PGS, and except for the transmitted PGS for childhood IQ, also all the transmitted PGSs (**Data S9**). Nine of the transmitted and 20 of the non-transmitted PGSs had high average stability, i.e., average of how often the trait was selected across repetitions of the cross-validation folds, to be selected to at least one of the components. The PGSs with high stability included the transmitted and both non-transmitted PGSs for childhood aggression, age at first birth, number of cigarettes per day, intelligence and smoking initiation, the transmitted and non-transmitted by father PGSs for ADHD and insomnia, both the non-transmitted PGSs for age at smoking initiation, EA, and self-reported health, the transmitted PGSs for MDD and wellbeing spectrum, and the non-transmitted by mother PGSs for ASD and childhood IQ.

Out of the 746 CpGs selected by the multi-omics model 204 (27.3%) were also selected by the single-omics DNA methylation model, and only cg03469862 (chr11: 68924853) was selected with high stability to any of the components in the multi-omics model (range = 0.10-0.92; **Data S2; Data S9**). We performed trait enrichment analyses against all reported associations in the EWAS atlas for all selected CpGs in the MB-sPLS-DA model. We observed the strongest enrichment for gender (OR = 3.90, $p = 3.97 \times 10^{-31}$), and breast cancer risk (OR = 342.60, $p = 1.44 \times 10^{-21}$; **Table S14**). These CpGs also

showed enrichment for e.g., neurological and developmental disorders, such as ASD and Parkinson's disease, cardiometabolic traits, such as obesity and Type II Diabetes, inflammatory disorders, such as respiratory allergies and ankylosis spondylitis, pre- and perinatal risk factors, such as preterm birth and maternal stress, and environmental exposures, such as organophosphate exposure (**Table S14**). All 90 metabolites selected by the MB-sPLS-DA model were selected with high average stability to at least one of the components, and only 11 metabolites showed low stability for selection in any specific component (**Data S9**).

Correlations of omics traits selected for childhood aggression in the multi-omics model

The average correlations between each omics layer in the multi-omics model, i.e., the correlation among all PLS variates of all components simultaneously, were $r = 0.19$ ($q = 2.13 \times 10^{-27}$) for PGSSs-DNA methylation, $r = 0.13$ ($q = 1.78 \times 10^{-12}$) for PGSSs-metabolomics, and $r = 0.15$ ($q = 3.76 \times 10^{-16}$) for DNA methylation-metabolomics. These correlations are lower than those observed for the cross-omics models on which the design matrix was based (**Table S4**), thus, this gives a stronger indication that omics traits from different omics levels capture largely independent information for childhood aggression. We observed high absolute correlations ($|r| \geq 0.60$) between 2 selected PGSSs, 14 CpGs, and 13 metabolite, that we summarize in five sets of correlational patterns (**Fig. 3; Data S10; Table S15**).

Correlation pattern 1 comprises high negative correlations of citric and fumaric acid with cg12886033 (chr1:65449013, r citrate = -0.61, r fumarate = -0.62), cg14508705 (chr1:172360182, r citrate = -0.61, r fumarate = -0.62), and cg11710553 (chr4:105892960, r citrate = -0.60, r fumarate = -0.61), and high negative correlations of fumaric acid with cg21432062 (chr3:4908643, $r = -0.60$), cg22848658 (chr6:135354586, $r = -0.60$), and cg15841349 (chr12:129348564, $r = -0.60$; **Fig. 3; Data S10; Table S15**). Both citric and fumaric acid are intermediates of the tricarboxylic acid (TCA) cycle. TCA cycle metabolites play a role in histone acetylation, and histone and DNA demethylation (Martínez-Reyes and Chandel 2020). The EWAs atlas only included cg21432062 (**Table S15**), where

hypermethylation of this CpG associates with inflammatory bowel disease (IBD). This is in line with studies that report decreased levels of citric and fumaric acid, and other TCA cycle-related metabolites, in the serum, urine, and lesion tissue samples of patients with IBD and related disorders (Ooi et al. 2011; Schicho et al. 2012; Dawiskiba et al. 2014). Thus, our negative correlational pattern seems in line with the observed hypermethylation for cg21432062 and decreased levels of citric and fumaric acid. The CpGs cg12886033, cg14508705, cg15841349, and cg22848658 are in the gene bodies of Long Intergenic Non-Protein Coding RNA 1359 (*LINC01359*), Dynamin 3 (*DNM3*), Glycosyltransferase 1 Domain Containing 1 (*GLT1D1*), and HBS1 Like Translational GTPase (*HBS1L*), respectively. CpGs in these genes associate with traits such as smoking, aging, down syndrome, and various types of cancers (**Table S15**).

The second correlational pattern is characterized by high negative correlations between isocitrate with cg05056638 (chr8:24800824, $r = -0.60$), cg08415582 (chr8:57030523, $r = -0.60$), cg11206167 (chr5:42924367, $r = -0.60$), and cg20704654 (chr20:30072118, $r = -0.61$; **Fig. 3; Data S10; Table S15**). All four CpGs associate with gender, with additional associations observed for cg05056638 with arsenic exposure (in utero) and Leukoaraiosis, and of cg20704654 with ageing (**Table S15**). The observation that these CpGs correlated highly with isocitrate is in line with research that reported inclusion of plasma isocitrate in the metabolomics profile that predicts chronological age in males and shows higher concentrations in older males (Rist et al. 2017).

Correlation pattern 3 contains the high positive correlation of homocysteine with cg13784456 (chr10:132970405, $r = 0.84$) and cg06144718 (chr10:133048392, $r = 0.75$; **Fig. 3; Data S10; Table S15**). These CpGs are included in the gene body of Transcription Elongation Regulator 1 Like (*TCERG1L*) and the EWAS atlas reported associations of CpGs in this gene with traits such as smoking, infertility, and various types of cancer (**Table S15**). We hypothesize that correlation pattern 3 may reflect the DNA methylation process itself, as homocysteine is involved in the methionine cycle that transfers the methionine methyl group to DNA methyltransferase (Selhub 1999).

The fourth correlational pattern includes high positive correlations between cg03469862 (chr11:68924853) with the transmitted PGS for ADHD ($r = 0.61$), 3-methoxytyrosine ($r = 0.63$), L-isoleucine ($r = 0.66$), L-leucine ($r = 0.65$), L-phenylalanine ($r = 0.70$), L-tryptophan ($r = 0.60$), L-valine ($r = 0.69$), L-glutamine ($r = 0.70$), L-tyrosine ($r = 0.63$), and L-serine ($r = 0.69$; **Fig. 3; Data S10; Table S15**). Look-up in the EWAS atlas showed that cg03469862 associates with prostate cancer and pre- and post-lenalidomide treatment in patients with Myelodysplastic syndrome with isolated deletion (5q) (**Table S15**). That higher DNA methylation of a CpG associated with prostate cancer and Myelodysplastic syndrome is associated with higher metabolite levels, and specifically higher amino acid levels, is corroborated by urinary metabolomics studies that report altered levels of 15 metabolites in patients with prostate cancer, including increased levels of valine (Lima et al. 2021), and of 29 metabolites in Myelodysplastic syndrome patients, including increased levels of valine (Yuan et al. 2021). In contrast, prostate cancer patients had decreased urinary levels of serine, leucine, glutamine, and tyrosine (Lima et al. 2021).

The final correlation pattern comprises a high negative correlation between the non-transmitted by father PGS for EA and cg09674340 (chr1:202509286, $r = -0.65$; **Fig. 3; Data S10; Table S15**). This CpG is located in the 1st exon of the Protein Phosphatase 1 Regulatory Subunit 12B (*PPP1R12B*) gene. CpGs in this gene associate with traits such as gender, smoking, and low birth weight (**Table S15**). The negative association of a smoking-related CpG with indirect genetic effects for EA is in line with a previous study that reported significant negative genetic correlations of indirect parental EA effect with smoking initiation, number of cigarettes per day, and smoking cessation (Wu et al. 2021). Similarly, the phenotypic association of low paternal educational attainment with low offspring birth weight is well-established (e.g., Meng and Groth 2018).

Discussion

This study comprised an integrative multi-omics analysis of childhood aggressive behavior to identify a multi-omics biomarker panel and to investigate the correlations among the omics traits

included in this panel. In our training data comprising 645 twins (cases = 42.0%, controls = 58.0%) we applied multivariate statistical methods to analyze and integrate transmitted and paternal and maternal non-transmitted PGSs for childhood aggression and for 14 traits genetically correlated with aggression (45 PGSs total), 78,772 CpGs, and 90 metabolites (Fig. 1). We build single-omics biomarker panels for each of the omics layers, that selected 31 PGSs, 1,614 CpGs, and 90 metabolites to discriminate between aggression cases and controls. The markers selected in single-omics models had poor predictive performance in our test ($N = 277$, cases = 42.2%, controls = 57.8%) and validation data ($N = 142$, cases = 45.1%, controls = 54.9%). The multi-omics panel selected 44 PGSs, 746 CpGs, and 90 metabolites, which also had poor predictive performance in our test and validation data.

We explored the pairwise correlations of the omics traits selected by the single-omics models. The average correlations between omics layers ranged from $r = 0.18$ to $r = 0.28$. Clustering analyses of each omics layer included in the pairwise correlations showed high overlap in the traits included in each cluster for the same omics layers. We frequently observed that transmitted and non-transmitted PGSs for the same traits were assigned to different clusters, though does not seem related to opposite correlations when comparing transmitted and non-transmitted PGSs, as all PGS traits show such patterns ($N_M = 49$, $N_{SD} = 23$, N range: 10-90). We showed that indirect genetic effects for ADHD, ASD, intelligence, smoking initiation, and self-reported health, correlate most strongly with buccal DNA methylation and urinary amino acid levels in children and that higher amino acid levels associate with hypomethylation in a cluster of CpG sites. We described five sets of correlational patterns with high absolute correlations ($|r| \geq 0.60$) of aggression-related omics traits selected by the multi-omics model. These multi-omics correlational patterns associate with a range of traits that link aggression-related omics traits to biological processes related to inflammation, carcinogens, ageing, sex differentiation, intelligence, and smoking.

This is the first multi-omics study that includes DNA methylation profiles from buccal and metabolomics in urine. Most of the earlier large-scale omics studies were conducted in blood samples. By obtaining omics measurements in easily accessible peripheral tissues (urine and buccal-cells) we could obtain multi-omics data for more individuals than most previous multi-omics studies for psychiatric traits, such as depression and suicide risk (Bhak et al. 2019) or post-traumatic stress disorder (Dean et al. 2019), that relied on small training samples (range: 126-165). In evaluating the validity of the PGS and multi-omics models in the clinical cohort, the non-transmitted PGSs could not be assessed, as no parental genotypes were available in the clinical cohort. Additional validation in cohorts with complete omics data that applied the same metabolomics and DNA methylation platforms are of large interest, but currently do not exist. Our design is optimal in nearly all other aspects, as the population and clinical cohorts collected all data, including biomarkers, at the same time, using the same arrays and platforms and with similar protocols.

The single- and multi-omics models also selected nearly all the PGSs, with only the transmitted PGSs for ASD, intelligence, childhood IQ, and self-reported health, and the non-transmitted by father PGSs for age at first birth, EA, insomnia, and loneliness not selected to the single-omics model, and the transmitted PGS for childhood IQ not selected to the multi-omics model (empirical design matrix). The high selection of transmitted PGSs to the biomarker panels likely reflect the genetic correlations of these traits with childhood aggression on which basis we included them in the current study (Ip et al. 2021). By including both transmitted and non-transmitted PGSs in the genomics block, this block captures the effect of parental genotypes on their offspring's rearing environment. The non-transmitted PGSs for various traits, including childhood aggression, were consistently retained in the single- and multi-omics models, which is in line with research that shows associations of parenting styles with childhood aggression (Masud et al. 2019). Previous research reported significant genetic correlations of indirect genetic EA effects with other complex traits (Wu et al. 2021), thus the high selection of non-transmitted PGSs in our model may also reflect their genetic correlations with childhood aggression.

In general, CpGs selected in the single- and multi-omics models were selected with low stability, i.e., the same CpGs was infrequently selected to the models across cross-validation folds and repeats. This low selection stability compared to the stability of PGSs and metabolites, might be explained by the large number of CpGs tested for inclusion in the models as compared to the number of metabolites or PGSs. The CpGs in the single- or multi-omics models did not overlap with the top differentially methylated CpGs for physical aggression as observed in buccal-cells (Cecil et al. 2018b), and were not significantly associated with aggression in a recent blood-based EWAS meta-analysis (van Dongen et al. 2021). Trait enrichment of the CpGs selected by the single- and multi-omics models reported enrichment of known aggression risk factors, such as socioeconomic status (Miller and Tolan 2019; Bellair et al. 2019; Hendriks et al. 2020), childhood malnutrition (Liu 2004; Vaughn et al. 2016), and pre- and perinatal risk factors (Van Adrichem et al. 2020). Also of interest is the enrichment of glucocorticoid exposure in CpGs selected by the single-omics model and the high correlation between cortisol and cg05153029 (chr20:19769815, $r = 0.61$), that associates with glucocorticoid exposure in the EWAS atlas (null design matrix MB-sPLS-DA model). Cortisol and other hypothalamus-pituitary-adrenal (HPA)-axis molecules have been implicated in aggressive behavior, suggesting a role of the stress response system in aggressive behavior (Hagenbeek et al. 2016). Epigenetic programming of the HPA-axis is influenced by pre- and perinatal factors, such as maternal behavior as observed in rats (Weaver et al. 2004), and maternal stress and early life adversity (Mulligan et al. 2012; Hompes et al. 2013; Jiang et al. 2019), and lower average global DNA methylation levels were reported in patients with Cushing's Syndrome (CS) in remission, a model for long-standing excessive glucocorticoid (cortisol) exposure (Glad et al. 2017). Thus, epigenetic mechanisms may mediate the association between cortisol and childhood aggression, similarly as the DNA methylation mediates the association between cortisol stress reactivity and childhood trauma (Wigglesworth et al. 2019).

The single- and multi-omics models selected all 90 LC- and GC-MS metabolites for inclusion, which might be explained by the low expression differences between aggression cases and controls

of the urinary amines and organic acids in this sample (Hagenbeek et al. 2020). Another plausible explanation regards the fact that we generated the metabolomics data on three targeted platforms, chosen because they cover relevant metabolites involved in neurotransmitter, inflammation, and steroid hormone pathways that associate with aggression (Hagenbeek et al. 2016). To date, no metabolomics platform can capture the entire metabolome. In addition, within a platform, technical challenges may cause compounds becoming undetectable or not quantifiable. This was the case for the steroid platform being less successful in quantifying (conjugated) sex hormones. Coverage could also be extended to include other metabolite classes, preferably in a hypothesis-free manner by employing non-targeted metabolomics platforms. The five sets of omics traits with high cross-omics correlations in the multi-omics model contained 13 metabolites. These metabolites comprised 8 amino acids (L-glutamine, L-isoleucine, L-leucine, L-phenylalanine, L-serine, L-tryptophan, L-tyrosine, and L-valine), 3 metabolites involved in the TCA cycle (citric acid, fumaric acid, and isocitrate), the dopaminergic trace amine 3-methoxytyrosine, and homocysteine, which is involved in cysteine and methionine metabolism. This is in line with previous studies reporting association of metabolites with aggressive behavior (Gulsun et al. 2016; Hagenbeek et al. 2016, 2020; Chen et al. 2020).

We explored how sensitive our results are to different specifications of the design matrices and found that these resulted in similar predictive abilities, but selected different numbers of only partially overlapping PGSs and CpGs (**Appendices C and D**). In line with expectations, the predictive ability of the null design matrix was slightly better than for the empirical design matrix, reflecting that such a model focuses on selecting discriminatory variables (Singh et al. 2019; Duruflé et al. 2020). We expected that the model with the full design model sacrificed predictive accuracy to select discriminatory variables that are also highly correlated, but this model had the lowest classification error rate as compared to the models with an empirical or null design matrix in the test and clinical data. Multi-omics models with differently specified design matrices differed not only in how many and which PGSs and CpGs were selected, but each multi-omics model provided unique insight into the correlations among the omics traits selected for their association with childhood

aggression. In the current study, we relied on the cross-validation results to select the number of traits and components in the model. However, to aid in biological interpretation, other choices can be made.

The low predictive accuracy of our single- and multi-omics models does not preclude the potential utility of these panels for, e.g. drug target identification; while common SNPs near drug targets often explain only small amounts of the phenotypic variance, pharmacological manipulations can be highly effective (Timpson et al. 2018). Thus, our description of the correlations of the PGSSs, CpGs, and metabolites advances our understanding how childhood aggression-related omics traits are interrelated and could lead to clues for potential drug targets, despite the low predictive accuracy of childhood aggression.

By adding a fourth broad exposome block, capturing known risk factors for childhood aggression, such as neighborhood variables (Miller and Tolan 2019), to the multi-omics model, the influence of environmental influences can be explored. Inclusion of other omics layers, such as the transcriptome, proteome, or a microbiome, may give other insights into the biological mechanisms of complex traits like childhood aggression. It should be noted that with the current method, inclusion of additional omics layers will cause an increase in the computational burden. Therefore, a different method to integrate multi-omics data or reduction of the computational burden might be considered. Future studies could consider reducing the number of parameters by including a smaller number of CpGs, by for example including only the top 1% or 5% most variable probes, or by selecting CpGs based on their known association with aggressive behavior, such as the top CpGs from the EWAS meta-analysis for aggressive behavior (van Dongen et al. 2021).

Conclusions

Our work entails one of the first applications of multi-omics approaches to childhood psychopathology. The approach we used was developed for dichotomous traits and classification

695 purposes but also gives insight into the how different omics levels associate with each other.
696 Classification was poor, whereas the multi-omics associations confirm well known associations
697 between childhood aggression and known risk factors as well as provide novel insight into the
698 correlational structure among omics traits from different omics levels.

699 Declarations

700 Acknowledgments

701 The Netherlands Twin Register (NTR) warmly thanks all twin families for their participation. LUMC-
702 Curium thanks all patients and their parents for participating, and clinicians for their support. NTR and
703 LUMC-Curium are grateful to all researchers involved in the data collection for the ACTION Biomarker
704 Study.

705 Funding

706 The current work is supported by the “Aggression in Children: Unraveling gene-environment
707 interplay to inform Treatment and InterventiON strategies” project (ACTION) and the Consortium on
708 Individual Development (CID). ACTION received funding from the European Union Seventh Framework
709 Program (FP7/2007-2013) under grant agreement no 602768. CID is funded through the Gravitation
710 Program of the Dutch Ministry of Education, Culture, and Science and the Netherlands Organization
711 for Scientific Research (NWO grant number 024-001-003). The Netherlands Twin Register is supported
712 by multiple grants from the Netherlands Organizations for Scientific Research (NWO) and Medical
713 Research (ZonMW): Netherlands Twin Registry Repository (NWO 480-15-001/674); Why some
714 children thrive (OCW Gravity program, NWO-024.001.003); Genetic influences on stability and change
715 in psychopathology from childhood to young adulthood (ZonMw 912-10-020); Twin family database
716 for behavior genomics studies (NWO 480-04-004); Twin research focusing on behavior (NWO 400-05-
717 717); Longitudinal data collection from teachers of Dutch twins and their siblings (NWO 481-08-011),
718 Twin-family-study of individual differences in school achievement (NWO-FES, 056-32-010),

Genotype/phenotype database for behavior genetic and genetic epidemiological studies (ZonMw Middelgroot 911-09-032); the Biobank-based integrative omics study (BIOS) funded by BBMRI-NL (NWO projects 184.021.007 and 184.033.111); the European Science Council (ERC) Genetics of Mental Illness (ERC Advanced, 230374, PI Boomsma); Developmental trajectories of psychopathology (NIMH 1RC2 MH089995); the Avera Institute for Human Genetics, Sioux Falls, USA; the Royal Netherlands Academy of Science Professor Award (PAH/6635) to D.I.B.. A research visit to the University of Toulouse (France) by F.A.H. was supported by the Faculty of Behavioural and Movement Sciences (FGB) Talent Fund (2019). J.D. is supported by the NWO-funded X-omics project (184.034.019). M.B. is supported by an ERC consolidator grant (WELL-BEING 771057, PI Bartels).

Conflict of Interest

C.K. was employed by Good Biomarker Sciences (Leiden, the Netherlands). E.A.E. was employed by the Avera Institute for Human Genetics (Sioux Falls, SD, United States). The remaining authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Ethical approval

The study was conducted according to the guidelines of the Declaration of Helsinki, and approved by the Central Ethics Committee on Research Involving Human Subjects of the VU University Medical Center, Amsterdam (NTR 25th of May 2007 and ACTION 2013/41 and 2014.252), an Institutional Review Board certified by the U.S. Office of Human Research Protections (IRB number IRB00002991 under Federal-wide Assurance- FWA00017598; IRB/institute codes), and the Medical Ethical Committee of Leiden University Medical Center (B17.031, B17.032 and B17.040).

Informed consent

Parents provided written informed consent for their children and twin parents provided written informed consent for their own participation.

743 Consent for publication

744 Not applicable.

745 Availability of data

746 The standardized protocol for large scale collection of urine and buccal-cell samples in the home
747 situation as developed for the ACTION Biomarker Study in children available at [http://www.action-](http://www.action-euproject.eu/content/data-protocols)
748 [euproject.eu/content/data-protocols](http://www.action-euproject.eu/content/data-protocols). The data of the Netherlands Twin Register (NTR) ACTION
749 Biomarker Study may be accessed, upon approval of the data access committee, through the NTR
750 (https://tweelingenregister.vu.nl/information_for_researchers/working-with-ntr-data).

Figures

Fig. 1. Overview of the biomarker identification approach for childhood aggression—details of statistical analyses and data included in each analysis.

We employed an analytical design comprising three phases: 1) single-omics analyses; 2) pairwise cross-omics analyses; and 3) multi-omics analyses. First, we performed univariate polygenic score (PGS) analysis in 70% of the twin data and built multivariate single-omics biomarker panels in the twin cohort, with 70% of the twin data for model training (training data), 30% of the twin data for model testing (test data), and the clinical cohort for model validation (validation data). Second, we examined the overall pairwise cross-omics correlations and the pairwise correlations of those omics traits selected by the single-omics models in the training data. Third, using the same data split for model training, testing and validation, we compared three multi-omics models, with different assumptions of the correlations among the omics traits, and describe the multi-omics correlations of the selected omics traits. We offer the analytical details in the **Methods** section.

Study Phase	Analyses	Design
1. Single-omics	<u>Univariate:</u> <ul style="list-style-type: none"> • Polygenic score analysis 	<u>Training data:</u> <ul style="list-style-type: none"> • 70% twin cohort ($N = 645$) • Cases: 271 (42.0%) • Controls: 374 (58.0%)
	<u>Multivariate – model training:</u> <ul style="list-style-type: none"> • Principal Component Analysis (PCA) • Partial Least Squares Discriminant Analysis (PLS-DA) • Sparse Partial Least Squares Discriminant Analysis (sPLS-DA) 	
	<u>Multivariate – model testing & validation:</u> <ul style="list-style-type: none"> • Predict out-of-sample case-control status • Receiver Operating Characteristic (ROC) analysis 	<u>Test data:</u> <ul style="list-style-type: none"> • 30% twin cohort ($N = 277$) • Cases: 117 (42.2%) • Controls: 160 (57.8%) <u>Validation data:</u> <ul style="list-style-type: none"> • Clinical cohort ($N = 142$) • Cases: 64 (45.1%) • Controls: 78 (54.9%)
2. Pairwise cross-omics	<u>All omics traits:</u> <ul style="list-style-type: none"> • Partial Least Squares (PLS) analysis <u>Selected omics traits:</u> <ul style="list-style-type: none"> • Partial Least Squares (PLS) analysis • Hierarchical clustering 	<u>Training data:</u> <ul style="list-style-type: none"> • 70% twin cohort ($N = 645$) • Cases: 271 (42.0%) • Controls: 374 (58.0%)
3. Multi-omics	<u>Model training:</u> <ul style="list-style-type: none"> • Multi-block Partial Least Squares Discriminant Analysis (MB-PLS-DA) • Multi-block sparse Partial Least Squares Discriminant Analysis (MB-sPLS-DA) 	<u>Training data:</u> <ul style="list-style-type: none"> • 70% twin cohort ($N = 645$) • Cases: 271 (42.0%) • Controls: 374 (58.0%)
	<u>Model testing & validation:</u> <ul style="list-style-type: none"> • Predict out-of-sample case-control status • Receiver Operating Characteristic (ROC) analysis 	<u>Test data:</u> <ul style="list-style-type: none"> • 30% twin cohort ($N = 277$) • Cases: 117 (42.2%) • Controls: 160 (57.8%) <u>Validation data:</u> <ul style="list-style-type: none"> • Clinical cohort ($N = 142$) • Cases: 64 (45.1%) • Controls: 78 (54.9%)

Fig. 2. Clustered heatmaps of the correlations obtained by the pairwise cross-omics Partial Least Squares (PLS) regression models including only the omics traits as selected by the single-omics sparse Partial Least Squares Discriminant Analyses (sPLS-DA).

We generated the hierarchical clustering using the Ward linkage algorithm on Euclidean distances of the PLS variates. For each dendrogram we identified two clusters (cluster 1 = pink, cluster 2 = blue). We have depicted positive correlations among the omics traits in red and negative correlations in blue. For the polygenic scores (PGSs), the ‘_NTm’ suffix denotes PGSs non-transmitted by mother, the ‘_NTf’ suffix denotes the PGSs non-transmitted by father, and childhood aggression is abbreviated as “aggression”, Attention-Deficit Hyperactivity Disorder as “ADHD”, Major Depressive Disorder as “MDD”, Autism Spectrum Disorder as “Autism”, Educational Attainment as “EA”, and wellbeing spectrum as “wellbeing”. For the metabolites, the ‘amines.’ prefix shows we measured these metabolites on the Liquid Chromatography Mass Spectrometry (LC-MS) amines platform, the ‘steroids.’ prefix shows we measured these metabolites on the LC-MS steroids platform, and the ‘OA.’ prefix shows we measured these metabolites on the Gas Chromatography (GC-) MS organic acids platform. **(a)** Correlation among the 1,614 CpGs and 90 metabolites included in the 3-component DNA methylation-metabolomics PLS model, where the selected CpGs are represented in the columns and the metabolomics traits in the rows. We included the cluster assignments and the full correlation matrix in **Data S4-S5**. **(b)** Correlations among the 36 PGSs and 90 metabolites included in the 2-component PGSs-metabolomics PLS model, where the selected PGSs are represented in the columns and the metabolomics traits in the rows. We included the cluster assignments and the full correlation matrix in **Table S9** and **Data S6**, respectively. **(c)** Correlation among the 36 PGSs and 1,614 CpGs included in the 2-component PGSs-DNA methylation PLS model, where the selected PGSs are represented in the columns and the CpGs in the rows. We included the cluster assignments and the full correlation matrix in **Data S7-S8**.

Fig. 3. High cross-omics correlations of the multi-omics traits identified in the 5-component multi-block sparse Partial Least Squares Discriminant Analysis (MB-sPLS-DA) model including the empirical design matrix

The outer ring depicts the PGSs, CpGs, and metabolites in yellow, pink, and green, respectively. For the polygenic scores (PGSs), Attention-Deficit Hyperactivity Disorder is abbreviated as “ADHD”, and Educational Attainment as “EA”, and the ‘_NT’ suffix denotes the PGSs non-transmitted by father. For the metabolites, the ‘amines.’ prefix shows we measured these metabolites on the Liquid

Chromatography Mass Spectrometry (LC-MS) amines platform, and the 'OA.' prefix shows we measured these metabolites on the Gas Chromatography (GC-) MS organic acids platform. The inner plot depicts the correlations among the omics traits. Here, we depict only high absolute correlations ($|r| \geq 0.60$) between traits of at least two omics layers, with blue lines reflecting negative correlations and red lines positive correlations. We averaged correlations across all components in the MB-sPLS-DA model. We included the full correlation matrix in **Data S10** and the correlational patterns in **Table S15**.
