18 **Abstract**

19 Despite involvement of B cells in the pathogenesis of immune-mediated diseases, biological
20 mechanisms underlying their function are scarcely understood. To overcome this gap, comprehensive
21 analysis of the B cell repertoire is essential. Here, we cataloged and investigated the repertoire of five
22 B cell subsets from 595 cases under immune-mediated diseases and health. CDR-H3 length among
23 naïve B cells was shortened among autoimmune diseases in an interferon signature-dependent manner.
24 VDJ gene usage was skewed especially in plasmablasts and unswitched-memory B cells of systemic
25 lupus erythematosus patients with frequent usage of VDJ genes used mainly in naïve B cells and not
26 unswitched-memory B cells of healthy controls. We developed a scoring system for this skewing, and
27 it correlated with peripheral helper T cell transcriptomic signatures and disease activity and decreased
28 after belimumab treatment. Moreover, genetic association analysis identified three molecules possibly
29 involved in somatic hyper-mutation processes in humans. Our multimodal repertoire analysis brings
30 new insights to B cell biology.

31

32 **Main**

33 B cells play critical roles in adaptive immunity, and their importance in immune-mediated disease
34 (IMD) pathogenesis is suggested by the overlap of genetic risk variants of IMDs to regulatory regions
35 in B cells^{1, 2} and by the clinical efficacy of B cell-targeted therapies in IMDs^{3, 4}. Thus, deeper
36 understanding of B cell biology could clarify IMD pathology.

37 To increase their diversity, B cell receptors (BCRs) are created by intrinsic genome-editing. In the
38 bone marrow, one V, D and J gene for one clonotype is selected (VDJ recombination), and random
39 deletions and insertions occur in the junctional regions. In the germinal center (GC), class switch
40 recombination and loading of somatic hypermutation (SHM) further increases BCR diversity. These
41 processes generate a vast variety of BCRs in an individual, a collection known as the “BCR repertoire”.
42 Heavy-chain complementarity-determining region 3 (CDR-H3) is the most variable region and central
43 to antigen specificity of BCRs.

44 For securing prompt defensive responses against diverse foreign pathogens, humans have evolved
45 a distinct immune system compared to other organisms⁵. Genetic adaptation in human populations has
46 resulted in strong immune responses against pathogens, but it was a trade-off against susceptibility to
47 autoimmunity⁵. The B cell immune system in humans is complex and has been elusive. It is now clear
48 that genetic determinants of individual difference among BCR repertoires as well as analysis of actual
49 differences in BCR repertoires among IMDs are essential for deeper understanding of B cell biology.

50 IMDs consist of autoimmune and autoinflammatory diseases⁶. Autoimmune diseases are
51 characterized by two prominent features: the emergence of autoantibodies and hyperactivity of
52 interferons (IFNs)⁶, although the relationship between these features remains elusive. For creation of
53 memory B cells and antibody secreting cells, affinity maturation through GC is a critical step. On the
54 other hand, previous studies revealed that those cell types can be differentiated in a GC-independent
55 manner⁷, a process termed “extrafollicular” maturation. Pathogenic autoantibodies are generated

through B cell extrafollicular reactions in systemic lupus erythematosus (SLE) and flares in SLE is characterized by the expansion of naive-derived activated effector B cells of extrafollicular phenotype⁸.⁹. The disease relevance of these features of abnormal B cell maturation in IMDs could be better understood if placed in the context of a large-scale dataset combined with other features.

We recently created a gene expression and genome sequence database containing a large variety of immune cells from 10 IMD patients as well as healthy volunteers². In this follow-up study, we focused on BCR features of 5 sorted B cell subsets that could be identified from RNA-seq data. We also examined their associations with transcriptomic, genetic, and clinical information. This largest-ever functional genomics dataset of immune cells from IMD patients enabled us to comprehensively explore BCR repertoire abnormalities in IMDs. We developed a scoring system of repertoire abnormalities in IMDs based on VDJ gene usage, the “Repertoire Naïveness (RN) Score”. The RN score showed significant association with the transcriptomes of specific T cell subsets and disease activity. Also, genetic association analysis of >500 plasmablast samples suggested previously unknown biology in nucleotide substitution mechanisms in SHM. Our multi-omics approach to a patient-derived, large-scale dataset generated new insights into B cell biology in both health and disease states.

Results

Profiling of BCR repertoires of IMD patients and healthy volunteers

We mapped BCR regions from RNA-seq reads of 5 sorted CD19⁺ B cell subsets: CD27⁻IgD⁺ naïve B cells, CD27⁺IgD⁺ unswitched memory B cells (USM B), CD27⁺IgD⁻ switched memory B cells (SM B), CD27⁻IgD⁻ double negative B cells (DN B) and IgD⁻CD27⁺⁺CD38⁺ plasmablasts (Fig. 1a). We extended our cohort from the previous report² and samples as follows: 136 patients with SLE, 90 patients with systemic sclerosis (SSc), 85 patients with idiopathic inflammatory myopathy (IIM), 147

patients with other IMDs and 137 healthy controls (HC), giving a total of 595 cases (Fig. 1a). For 22 SLE patients, samples were also obtained after a half-year treatment with belimumab, a biologic targeting B-cell activating factor (BAFF). After mapping and quality control (Methods), 5.8 million productive unique CDR-H3 clonotypes were identified from 2,893 samples. On average, 2,801 distinct productive clonotypes were identified in each sample (Extended data Fig. 1a). More than 5,000 BCR-derived reads were identified per million RNA-seq reads in each subset (median), and in plasmablasts it reached 1.1×10^5 reads (Fig. 1b), reflecting their specialized role in secreting antibodies.

As naïve B cells are expected to have few SHM, the mutation frequency can reflect the error rate in PCR or sequencing steps. The SHM frequency in V genes in naïve B cells was well controlled at 0.15% (median), in clear contrast to 6.7% (median) in plasmablasts (Fig. 1c). The number of shared CDR-H3 sequences was substantially larger in comparisons of the same individuals than in the comparisons of different individuals (Fig. 1d). The greatest degree of sharing was observed among the samples from the same individual and the same subset at different time points, indicating the valid reproducibility of our BCR repertoire dataset (Fig. 1d). Equivalent to the previous single cell BCR analysis that classified more than 99% of IgG⁺ and 98% of IgA⁺ cells as memory cells¹⁰, IgG or IgA were rarely detected (0.4%) in naïve B cells in our dataset (Fig. 1e). Together, our dataset captured biologically reasonable characteristics of BCR repertoires and enabled deep phenotyping of repertoires among IMDs.

In order to evaluate the influence of the number of reads for BCR repertoire characterization, we down-sampled the number of reads from plasmablast RNA-seq data as well as the BCR-seq data of peripheral blood mononuclear cells from the previous study¹¹ and mapped BCR regions in the same way. These analyses revealed the strong influence of the number of reads on the number of identified CDR-H3 clonotypes, in clear contrast to stable quantification of CDR-H3 length, V gene usage and isotype frequency even with shallow depth (Extended data Fig. 1b). Thus, in our following RNA-seq based BCR repertoire analysis, we focused on these relative features, rather than analyzing whole

104 clonotypes.

105

106 **In autoimmune diseases, CDR-H3 length is shortened in naïve B cells in an interferon signal**
107 **strength-dependent manner**

108 CDR-H3 loop length is one of the classic indices for the assessment of repertoire bias¹². When we
109 compared CDR-H3 length with HC, marked shortening of CDR-H3 lengths in naïve B cells (by more
110 than 1 amino acid) and DN B cells among autoimmune diseases were observed (Fig. 2a; Extended data
111 Fig. 2a). Conversely, CDR-H3 lengths in USM B cells and plasmablasts of SLE patients were longer
112 than those in HC (Fig. 2a; Extended data Fig. 2a). Among the sections of the CDR-H3 region,
113 lengthening in plasmablasts was observed in germline-coded regions but not in junction regions, in
114 contrast to shortening in overall sections in naïve B cells (Fig. 2b; Extended data Fig. 2b).

115 Observations so far were only from productive sequences. Non-productive sequences, which refer
116 to the sequences with a frameshift or stop codon, can be used as a means of studying the pre-selection
117 repertoire¹³. In our dataset, shortening of CDR-H3 lengths among autoimmune diseases was observed
118 in non-productive sequences of naïve and memory B cells (Extended data Fig. 2c). Thus, together with
119 the observed shortening of overall CDR-H3 sections in productive sequences, short CDR-H3
120 clonotypes may be generated before selection of mature naïve B cells (e.g., during the process of VDJ
121 recombination and nucleotide insertion/deletion at the junctions). This observation is analogous to
122 previous reports of shortening of CDR3 length in pre-selection T cell receptors among type 1 diabetes
123 patients¹³. Moreover, CDR-H3 lengthening in germline regions of plasmablasts and USM B in SLE
124 may be the consequence of skewed VDJ gene usage as described in the next section.

125 CDR-H3 shortening was especially prominent in naïve B cells from diseases with high IFN
126 signatures (Fig. 2a; Extended data Fig. 2d), although CDR3 length was not as divergent among light
127 chains (Extended data Fig. 2e). To investigate further, we tested the association of gene expression and

128 CDR-H3 length in naïve B cells in each disease and subsequently performed meta-analysis in order to
129 avoid the confounding of disease effects (Methods). Genes associated with a short CDR-H3 length
130 were significantly enriched in IFN signature genes (ISG, Fig. 2c, d), and the association was observed
131 in each autoimmune disease (Extended data Fig. 2f). CDR-H3 length in naïve B cells was also
132 significantly associated with ISG expression in 4 other B cell subsets, indicating the association of
133 generalized IFN activity itself with CDR-H3 length (Extended data Fig. 2g). Strong negative
134 correlation between CDR-H3 length and IFN activity was characteristic of naïve B cells among 5 B
135 cell subsets (Fig. 2e). These results suggested a role of IFN signaling at the early stage of B cell
136 development, which is consistent with previous findings of IFN-induced abnormal B cell maturation
137 in bone marrow of SLE¹⁴.

138

139 **Skewed gene usage in autoimmune diseases suggested an abnormal repertoire maturation** 140 **process**

141 It was previously suggested that there was differential usage of VDJ genes according to B cell subsets¹⁵,
142 ¹⁶. As these reports were limited to one healthy female¹⁵ and inbred strain of mice, C57BL/6¹⁶, the
143 generalizability of this finding in a large population has been elusive. In our cohort, gene usage
144 preference among 5 B cell subsets was also observed (Extended data Fig. 3a). More surprisingly, by
145 principal components analysis (PCA) of VDJ gene usage, samples were clearly separated according to
146 cell types (Fig. 3a). The separation pattern reflected the lineage relationships among the subsets, and
147 they were arranged similarly to the flow-cytometric plots according to CD27 positivity and IgD
148 positivity (Fig. 3a). This observation is analogous to previously reported clear separation of 3 B cell
149 subsets by PCA of VDJ use in C57BL/6 mice¹⁶. Those results strongly suggested that B cell selection
150 was based on VDJ gene segments independent of the sequence of their antigen-binding regions in
151 humans.

152 It has been shown that there is skewed usage of the IGHV in IMDs¹⁷ with dependence on the stage
153 of disease¹⁸, although the sample size has been limited. Notably, in the PCA space, the gene usage
154 signature was drastically skewed in the negative direction of the CD27 axis in SLE among USM B and
155 plasmablasts (Fig. 3a; Extended data Fig. 3b). With regard to IIM and SSc, the repertoire skewed in
156 the same direction in the PCA space in USM B, but not obviously in plasmablasts (Extended data Fig.
157 3b). In case-control comparisons, many differentially used genes were identified especially in
158 autoimmune diseases (Fig. 3b). In parallel with the findings in the PCA space, VDJ gene usage
159 differences between SLE and HC in USM B, as well as plasmablasts, showed clear agreement with
160 gene usage differences between naïve B and USM B in HC (Fig. 3c). These results indicated that the
161 majority of observed differential gene usage in SLE was associated with the global abnormality in B
162 cell maturation process, rather than the consequence of specific antigens.

163 Based on the observed skewing in VDJ gene usage in autoimmune diseases toward a CD27 negative,
164 “naïve like” repertoire, we next developed a score to quantify such skewing based on its VDJ gene
165 usage. We termed this factor the “Repertoire Naïveness (RN) Score”. Briefly, the RN score is
166 calculated as the sum of the product of normalized VDJ gene usage and the size of its effect, defined
167 by naïve B versus USM B comparisons in HC (Methods, Supplementary table 1). As we defined the
168 effect sizes of each gene only using HC samples, this score can be applied to inter-disease comparison
169 without bias. Consistent with the appearance in PCA, our RN score was the highest among naïve B
170 cells followed by DN B cells, and the highest among SLE patients in USM B or plasmablasts (Extended
171 data Fig. 3c, d). To validate our approach, we adopted the same scoring system to the BCR-seq data
172 derived from sorted B cells from human tonsils in a previous study¹⁹. The RN score was clearly high
173 in naïve B cells and low in memory B cells (Extended data Fig. 3e).

174 As reported previously²⁰, the use of each VDJ gene was associated with different CDR-H3 lengths
175 (Extended data Fig 3f). The genes associated with an extended CDR-H3 were preferentially used by

plasmablasts in SLE (Extended data Fig. 3g). Thus, the extended CDR-H3 length in SLE in this subset is associated with abnormal VDJ gene usage, at least in part.

The repertoire abnormality in autoimmune diseases may be associated with the extrafollicular pathway and specific subpopulations of Th1 cell

Extrafollicular maturation of plasmablasts has been reported as a hallmark of SLE⁸. Next, we assessed the association of the observed “naïve like” repertoire and the extrafollicular maturation. Although extrafollicular maturation-derived antibody secreting cells undergo SHMs, they are expected to have less SHMs^{7, 9, 21} compared to GC-derived cells. In line with this notion, the frequency of SHMs in plasmablasts was significantly lower in SLE patients than in HC (Extended data Fig. 4a). Furthermore, it showed a significant negative correlation with the RN score (Fig. 4a). To examine the relationship in clonotype levels, we divided BCR clonotypes into bins according to the frequencies of SHMs and calculated RN scores in each bin. In this comparison, we observed that clonotypes with a lower number of mutations showed higher RN scores (Fig. 4b). Taken together, naïve-like gene usage in plasmablasts is associated with a low load of SHM. Reflecting the accumulation of mutations with aging¹¹, SHM frequencies in plasmablasts showed a significant positive correlation with aging ($p < 2 \times 10^{-16}$), although the RN score was not affected by aging ($p > 0.05$, Extended data Fig. 4b). The RN score distinguished SLE patients from HC more accurately than did the SHM frequency (Extended data Fig. 4c). Thus, although well correlated, the RN score might reflect disease-associated pathways better than the SHM frequency.

We next compared the RN scores of 136 SLE patients focusing on the gene expression of 27 immune cell subsets that were obtained from the same patients. The number of genes that showed a significant correlation with the RN score was the largest in Th1 cells for both plasmablasts and USM B (Fig. 4c). The top associated genes in Th1 cells included *PDCDI*, *TOX* and *ICOS*, which are hallmarks of

recently identified peripheral helper T cells (Tph)²² (Fig. 4d). Indeed, the Th1 genes associated with RN score showed significant concordance with the direction of change in the differential expression analysis between PD-1^{hi} versus PD-1^{lo} T cells from the original report²² (Fig. 4e). Thus, the Th1 genes associated with the RN score may reflect the expansion of Tph-like subpopulation among Th1 cells. The Tph gene expression score in Th1 cells (Tph1 score, Methods) was high in SLE (Extended data Fig. 4d), consistent with the reported expansion of Tph population²³, particularly with Th1 phenotype²⁴, in SLE. The Tph1 score showed a strong correlation with the RN score in SLE, both in USM B and plasmablasts (Extended data Fig. 4e). Correlation of these two scores was also prominent in USM B in IIM, although the correlation in plasmablasts was lower than that in SLE. These results may reflect the shared and distinct pathogenicities among autoimmune diseases. The association of Tph1 score and RN score was also validated in our independent SLE cohort²⁵ (Extended data Fig. 4f). Although IFN signal strength was also correlated with RN scores (Extended data Fig. 4g), this association was mostly mediated by the Tph1 score (Fig. 4f). The direct effect of IFN signal strength on RN score was not significant ($p = 0.21$) in the mediation analysis (Fig. 4f). This result indicated the role of IFN on Tph cell expansion. The proposed function of Tph cells is that they provide help to B cells outside the GC^{22, 23}. Collectively, associations of RN score with low SHM frequencies and high Tph1 score support the notion that the naïve-like repertoire in IMDs is a consequence of excess extrafollicular maturation.

The RN score of USM B correlated significantly and positively with the expression of *TBX21* in USM B, which codes for T-bet (Extended data Fig. 4h). As T-bet⁺ B cells reportedly have distinct functions²⁶ and are associated with autoimmunity²⁷, this naïveness-associated USM B population might play a role in autoimmune pathogenesis.

Repertoire abnormalities are associated with disease activity in SLE

We next tested the association of BCR repertoire abnormalities and disease activity in SLE. RN scores in plasmablasts and USM B showed significant positive correlations with SLEDAI-2K, a measure of SLE disease activity (Fig. 5a), and these associations were still significant after adjusting for Tph1 scores ($p = 1.3 \times 10^{-3}$, 1.7×10^{-3}) and ISG scores ($p = 5.3 \times 10^{-4}$, 2.3×10^{-5}), indicating the clinical relevance of RN scores. In addition, RN score in plasmablasts significantly correlated with total IgG concentrations in sera (Extended data Fig. 5a).

We next asked whether specific V, D or J gene usage was associated with disease activity. In SLE, among the 5 B cell subsets, IGHV4-34 usage in USM B showed by far the most significant positive association with SLEDAI-2K ($p = 3.9 \times 10^{-10}$, Fig. 5b, Extended data Fig. 5b). Although the expansion of antibody secreting cells with IGHV4-34 in acute SLE has been reported⁹, the clinical relevance of its usage in USM B has not been clarified. IGHV4-34 is a V gene that is predominantly used in naïve B cells (Extended data Fig. 3a) and its usage explained 28% of the variance of RN score in USM B (Extended data Fig. 5c). Mediation analysis indicated that over one-half of the association between RN scores in USM B and SLEDAI-2K was mediated by IGHV4-34 usage. This contrasted with the independent direct association of RN scores in plasmablasts with SLEDAI-2K (Extended data Fig. 5d). Thus, repertoire naïveness in SLE may be associated with disease activity partly via high usage of IGHV4-34 in USM B.

It has been reported that IGHV4-34 has AVY and NHS motifs that are associated with autoimmunity²⁸. Mutations in these motifs abrogate its autoreactivity and only such clones without autoreactivity are selected for maturation under healthy conditions^{28, 29}. IgG B cells without mutations in these motifs from IRAK4- and MYD88-deficient patients demonstrated reactivity to autoantigens as well as binding to commensal bacterial antigens²⁹. In our dataset, NHS and AVY motifs were significantly more conserved without mutations in SLE USM B compared to HC as well as in

plasmablasts (Fig. 5c). Thus, IGHV4-34 clonotypes in SLE might feature binding to autoantigens.

Belimumab attenuated abnormal repertoire in SLE

For SLE, the BAFF inhibitor belimumab is one of the two biologics that has been approved by the United States Food and Drug Administration³. In SLE, BAFF is induced by type I IFN stimulation and supports the survival and differentiation of autoreactive B cells^{30, 31}. To assess the effect of BCR modifications, we tested the BCR repertoire before and after treatment with belimumab in 22 cases of SLE. Belimumab effectively reduced SLEDAI-2K and increased complement levels in our cohort (Fig. 5d). In order to assess the overall trend, we projected cases before and after belimumab treatment on the same PCA space as Fig. 3a. Belimumab treatment significantly changed the repertoire of USM B against the naiveness-associated direction, but not in the other subsets (Fig. 5e, f). Belimumab significantly reduced the RN scores in USM B, although we detected no effects on Tph1 scores or IFN scores (Fig. 5d). As to IGHV4-34, belimumab significantly reduced the fraction of nonmutated AVY/NHS motifs in USM B and plasmablasts (Extended data Fig. 5e). Thus, together with its major effect on the USM B repertoire, belimumab also reduced the autoimmune-associated fraction of BCRs in plasmablasts.

We next divided all cases in our cohort, including healthy controls, into 6 clusters based solely on the usage of VDJ genes of USM B and plasmablasts that were utilized for RN score calculation (Extended data Fig. 5f). The largest cluster (cluster 1) mostly consisted of autoimmune disease patients; these subjects showed higher RN scores, Tph1 scores and IFN scores than the others. Among SLE patients, subjects in this group responded better to belimumab than did others when assessed by delta SLEDAI-2K after a half-year treatment ($p = 0.007$, Extended data Fig. 5g). These results indicated that the BCR repertoire abnormality reflected clinical heterogeneity within and between diseases.

271

272 **Altered isotype usage in SLE is partly influenced by abnormal repertoire maturation**

273 With regard to isotype frequency, significant skewing was also observed in IMDs compared with HC
274 (Extended data Fig. 5h). As the frequencies of many isotypes were altered in SLE plasmablasts, we
275 assessed their association with RN scores in plasmablasts. The association between isotype frequencies
276 and RN scores differed according to class (Extended data Fig. 5i). A substantial proportion of the
277 decrease in IgA2 frequency and the increase in IgG1 frequency in SLE could be explained by the high
278 RN score in SLE. That finding might indicate an association with the extrafollicular pathway, although
279 the increase in IgA1 frequency in SLE seemed to have no association with this pathway (Extended
280 data Fig. 5i). Thus, the increase in IgA1 frequency in SLE might be due to other pathways, such as
281 involvement of mucosal immunity as suggested previously^{17, 29}.

282

283 **Analysis of genetic association reveals molecules associated with somatic hyper-mutation biology**

284 Finally, we tested the association of BCR repertoire features with genetic polymorphisms. For VDJ
285 gene usage, we observed significant cis-regulatory effects (Fig. 6a). This result is concordant with a
286 classical twin study that showed significant heritability in V gene usage³². Significant genetic
287 association was observed only in V gene usage, and not in D and J gene usage (Extended data Fig. 6a).
288 The genetic association with V gene usage was highly concordant among 5 B cell subsets (Extended
289 data Fig. 6b), indicating that polymorphisms have effects on gene preference at the step of VDJ
290 recombination.

291 SHM is likely a random process. However, the unevenness of nucleotide substitution patterns
292 indicates complex biological processes in the substitution process³³. To assess the association of SHM
293 substitution patterns and genetic polymorphisms, we developed a new framework, i.e., SHM-QTL
294 analysis. In this analysis, we quantified nucleotide substitution pattern frequencies in plasmablasts of

each subject and assessed its genetic association (Methods). In this way, we identified two loci that showed significant genome-wide association with SHM patterns (Fig. 6b). Of note, in the *NUGGC* locus, 3 conditionally independent lead variants were identified, and they were associated differently with nucleotide substitution patterns (Fig. 6c, Extended data Fig. 6c). Two of the 3 lead variants were missense variants and the other one was also in tight LD ($r^2 = 0.96$) with a missense variant. These missense variants were located in different exons of *NUGGC*, and 2 of the 3 variants were estimated to be located on the surface of the protein (Extended data Fig. 6d). Thus, these variants could change the interaction of *NUGGC* with other molecules. In the *RRM2B* locus, the lead variant was in high LD with a missense variant of *RRM2B* (Fig. 6d, rs1037699, $r^2 = 0.87$), and conditioning by the missense variant cancelled the association of the lead variant (Fig. 6e), thus indicating the association of this missense variant. In the *RRM2B* locus, conditioning analysis revealed the other associated variant, rs892503. Although this variant was not in LD with any missense variant, the residual association showed nearly perfect co-localization with eQTL effects in plasmablasts for *AP002852.2* (Fig. 6e, $\text{coloc}^{34} PP. H4 = 0.985$), long non-coding RNA (lncRNA) expressed almost exclusively in memory B cells and plasmablasts (Extended data Fig. 6e). The identified 5 independent variants contributed to substitution patterns differently (Extended data Fig. 6f), and they explained 21.1% of SHM substitution diversity in total (Methods). To our knowledge, this is the first assessment of genetic effects on SHM substitution patterns and highlighted three molecules that may be associated with SHM biology in humans.

Discussion

In this report, we characterized BCR repertoire abnormalities in IMDs using a large cohort of 595 cases. Our multi-layer dataset enabled us to link the BCR repertoire to other layer information, including transcriptome of multiple immune cell types, genetic polymorphisms and clinical

information.

We identified marked shortening of CDR-H3 length in naïve B cells of autoimmune disease patients in an IFN signal strength-dependent manner, as well as lengthening in plasmablasts of SLE patients. Shortening of BCR CDR-H3 length in peripheral blood mononuclear cells of SLE patients had been reported³⁵. Antibodies with long CDR-H3 length were associated with autoreactivity³⁶ and long CDR-H3 length in class switched clonotypes in SLE was also reported¹⁷. Our results are consistent with all of these seemingly contradicting reports and reinforce the importance of using sorted B cells for repertoire analysis¹⁵.

In gene usage analysis, we observed a global pattern of skewness in specific subsets of IMDs as quantified with the RN score. This score can measure extrafollicular maturation based on the observation of its association with naïve-like gene usage, low SHM load and its correlation with Tph signature gene expression in Th1 cells. Another possible explanation includes the defects in GC selection by formation of spontaneous GCs as suggested in lupus model mice and patients^{37,38}, which might result in a similar BCR phenotype. Although the elucidation of the precise intermediate process is a future problem, the observed significant association of these scores with clinical parameters and their responses to clinically effective treatment suggested the disease relevance of these BCR repertoire-based measures and their possible utility for clinical practice such as patient stratification. Interestingly, in SLE patients, the repertoires of USM B and plasmablasts seemed to be skewed similarly in response to Tph expansion. This was in contrast to the observation of similar associations in USM B but less so in plasmablasts in IIM. This result may suggest the existence of a “gate-keeper” for plasmablast maturation that is defective in SLE. Together with CDR-H3 length analysis, our results support the notion that the break of tolerance occurs both in central and peripheral checkpoints in SLE^{39,40}. Also, our analysis supported direct and indirect associations of IFN signaling with both of these checkpoints.

343 In SHM-QTL analysis, we identified 3 molecules possibly associated with SHM biology. SHM is
344 triggered by activation-induced cytidine deaminase (AID)⁴¹. Although multiple molecules are involved
345 in subsequent DNA damage response⁴², the roles of 3 identified molecules in this study has not been
346 well known. *NUGGC*, Nuclear GTPase, Germinal Center Associated, was first identified as a GTPase
347 expressed in germinal center B cells. It inhibits the function of AID in cell lines⁴³. Interestingly,
348 NUGGC-deficient mice reportedly have a substantial increase in mutations at G:C base pairs⁴⁴ and
349 experience altered patterns of SHM. These data, together with our findings, strongly suggest an
350 association of this molecule in DNA repair in SHM processes in humans. *RRM2B* has been reported
351 to repair DNA damage in a TP53-dependent manner⁴⁵, although its function in B cells has not been
352 known. RRM2B may also be associated with repair of DNA damage induced by AID.

353 In summary, our large-scale BCR repertoire analysis provided an overview of B cell abnormalities
354 in IMDs and revealed the presence of new molecules associated with SHM biology in health. This
355 analysis exemplifies the usefulness of multi-omic human data for finding new features in cellular
356 biology.

Fig. 1: Study design and quality features of our dataset.

a, Study design used in this report. Sample numbers after quality control are presented under each disease. **b**, Number of RNA-seq reads aligned to BCR regions per million reads in 5 B cell subsets. **c**, Comparison of the per base mutation frequency in the V gene region of 5 B cell subsets. **d**, Comparison of clonotype overlap frequencies between samples according to the individual or the subset being the same or different. “The same individual, the same subset” comparison was performed with SLE samples before and after treatment with belimumab 6 months apart. *P* values were calculated with two-sided Mann–Whitney *U*-test. **e**, Comparison of median isotype frequencies in each subset among healthy controls.

Fig. 2: In autoimmune diseases, CDR-H3 length is shortened in naïve B cells in an interferon signal strength-dependent manner.

a, Comparison of CDR-H3 length between IMDs and HC. The difference between HC and each disease was tested with linear regression, adjusting for age and batch effects. *, $p < 0.05/50$. **b**, Comparison of germline and junction part length of CDR-H3 region (see also Extended data Fig. 2b). The differences between HC and SLE were tested with linear regression, adjusting for age and batch effects. *, $p < 0.05/10$. **c**, Association of naïve B cell gene expression with naïve B cell CDR-H3 length. Fixed effect meta-analysis p values and effect sizes are plotted (Methods). Genes that attained Bonferroni-adjusted $p < 0.05$ are marked red. Genes in “HALLMARK_INTERFERON_ALPHA_RESPONSE” gene set from MSigDB are marked with diamonds. **d**, Gene set enrichment analysis. Results of genes significantly negatively associated with CDR-H3 length in naïve B cells. FDR, false discovery rate. **e**, Correlation between IFN score and CDR-H3 length in 5 B cell subsets. Mean values among HC, SLE, SSc, and IIM are marked with large points. The color of each point indicates the clinical diagnosis as illustrated in Fig. 1a. Pearson’s r is provided.

Fig. 3: Skewed gene usage in autoimmune diseases suggested an abnormal repertoire maturation process.

a, Principal component analysis plot of all samples based on VDJ gene usage. Centroids of HC, SSc, IIM, and SLE in each subset are marked with large points. **b**, Skewed gene usage in IMDs compared to HC. In each disease-subset (column), gene usage (row) was compared with HC after adjusting for age and batch effects. Effect sizes of linear model comparison are plotted if the difference was statistically significant (FDR < 0.05). Only genes that attained FDR < 0.05 in at least one comparison are shown. **c**, Comparison of β estimates in usage comparison between naive B vs USM B in HC (y axis) and SLE vs HC (x axis) in USM B (left) or plasmablasts (right). Each plot corresponds to each VDJ gene. Genes that attained FDR < 0.05 in SLE vs HC comparison are marked red. Grey bars indicate 95%CI. Pearson's r and its significance are provided.

Fig. 4: Association of the repertoire abnormality in autoimmune diseases with a low load of mutations and specific subpopulations in Th1 cells.

a, Correlation of RN score and SHM frequency in the V gene region of plasmablasts. *P* values were calculated with linear regression adjusting for diagnosis, age and batch effects. Mean values among HC, SLE, SSc, and IIM are marked with large points. The color of each point indicates the clinical diagnosis as illustrated in Fig. 1a. **b**, RN scores of clonotypes stratified by SHM frequency. In each disease, clonotypes for which ≥ 200 nucleotides in the V gene were sequenced were aggregated and divided into bins according to mutation frequency in the V gene region. In each bin, RN score was calculated based on VDJ gene usage. **c**, Number of significantly associated genes with RN score in USM B (top) and plasmablasts (bottom) among expressed genes in each immune cell. Full description of subset names is in Table S3. **d**, Association of gene expression in Th1 cells and RN score in USM B. Significantly associated genes are colored red. **e**, Comparison of the effect size estimates of Th1 expression versus RN score comparison in our cohort (Y-axis) and PD-1^{hi} versus PD-1^{low} T cells comparison in the data by Rao, *et al*²² (X-axis). Only genes significantly associated with RN scores in our cohort were included for the analysis. *P* values were calculated by the binomial test for concordance of the direction of effect size estimates. logFC, log fold change. **f**, Mediation model representing the relationships among IFN score, Tph1 score and RN score in plasmablasts among SLE patients. The bootstrapped indirect effect was 0.26 (95% CI, 0.14-0.39; $p = 2 \times 10^{-4}$). Thus, the indirect effect was statistically significant.

Fig. 5: Repertoire abnormalities are associated with disease activity in SLE and attenuated by belimumab treatment.

a, Correlation between RN scores and SLEDAI-2K among SLE patients. Pearson's r and its significance are provided. **b**, Association of VDJ gene usages among 5 B cell subsets and SLEDAI-2K. Significantly associated genes ($FDR < 0.05$) are red. **c**, Comparison of mean IGHV4-34 usage (top) and percentage of clonotypes with mutations in the NHS motif (middle) or the AVY motif (bottom) among IGHV4-34 clonotypes. For usage comparison, the differences between HC and each disease were tested with linear regression adjusting for age and batch effects. Bars indicate 2SE. For mutation comparison, Fisher's exact test comparing the number of mutated/nonmutated clonotypes between HC and each disease was performed in each subset. *, $p < 0.05/15$. **d**, Comparison of clinical parameters and scores before and after treatment with belimumab. Patients are colored according to improvement in SLEDAI-2K after treatment (red, ≥ 4 ; orange, 1-3; grey, ≤ 0). Paired Wilcoxon signed-rank test. **e**, Change in BCR repertoire after belimumab treatment. Paired samples before and after treatment were connected on the same PCA space as Fig. 3a. **f**, Belimumab treatment effects on PC scores by fitting the linear mixed model. Bars indicate 95% CI.

Fig. 6: Analysis of genetic association reveals molecules associated with somatic hyper-mutation biology.

a, P values of V gene usage-QTL analysis in naïve B cells. P values of QTL analysis for 43 V genes are plotted together. Red line indicates the significance threshold ($p < 5.0 \times 10^{-8}/43$). **b**, P values of SHM-QTL analysis. P values for QTL analysis for 6 patterns of mutations are plotted together. Red line indicates the significance threshold ($p < 5.0 \times 10^{-8}/6$). **c**, Regional association plot of *NUGGC* locus. Associations of 5 mutation patterns that attained genome-wide significance in this region are plotted. Large marks correspond to 3 independent missense variants that are also (or in tight LD with) lead variants. **d**, Regional association plot of *RRM2B* locus. Associations of 3 mutation patterns that attained genome-wide significance in this region are plotted. A large mark corresponds to the missense variant for *RRM2B* that is in high LD with the lead variant. **e**, Residual association in *RRM2B* locus after conditioning by rs1037699 (top) and eQTL p values for *AP002852.2* expression in plasmablasts (bottom).

446 **Methods**

447 **Criteria for patient inclusion/exclusion**

448 The SLE cohort was comprised of patients who had attended the Department of Allergy and
449 Rheumatology at the University of Tokyo Hospital, Division of Rheumatic Diseases at National Center
450 for Global Health and Medicine or Immuno-Rheumatology Center at St. Luke's International Hospital,
451 who met the 1997 revised version of ACR SLE criteria⁴⁶. Of the enrolled 136 patients, 88 cases had
452 active disease with SLEDAI-2K ≥ 4 . The other cases were inactive at the time of blood withdrawal.
453 Patients administered cyclophosphamide or rituximab within one year or taking ≥ 21 mg/day
454 prednisolone were excluded from this analysis. For 22 patients, belimumab was initiated after the
455 collection of the samples, and samples after a half-year treatment were also collected. To assess the
456 drug's effect, cases with concomitant prednisolone increase ≥ 5 mg/day or concomitant addition of
457 other immunosuppressants were excluded.

458 The SSc cohort was comprised of patients who had attended the Department of Allergy and
459 Rheumatology at the University of Tokyo Hospital or Department of Rheumatology at Tokyo
460 Metropolitan Komagome Hospital, who met the 2013 American College of Rheumatology (ACR)/
461 European League Against Rheumatism (EULAR) classification criteria for Systemic Sclerosis⁴⁷.
462 Patients taking ≥ 21 mg/day of prednisolone were excluded from this analysis.

463 The IIM cohort was comprised of patients who had attended to the Department of Allergy and
464 Rheumatology at the University of Tokyo Hospital or Division of Rheumatology at the Jikei University
465 Hospital. They met standards defined by the Bohan and Peter criteria^{48, 49}, or the European
466 Neuromuscular Center criteria⁵⁰, or the Sontheimer criteria⁵¹ or the Griggs criteria⁵². Patients taking $\geq$
467 12 mg/day prednisolone were excluded. Of the 85 patients, 36 cases had active disease and required
468 subsequent initiation or an increase of immunomodulatory drugs.

469 The inclusion criteria for HC were people with no apparent co-morbidities, no direct family history

of autoimmune diseases and no use of prescription drugs or supplements. Age and sex were matched with the patient cohort as much as possible. For 30 HC cases, only naïve B cells among 5 B cell subsets were collected and utilized for the analysis. For the remaining 107 cases, 5 B cell subsets were collected.

Patient inclusion/exclusion criteria for the other diseases were described in detail in our first report².

Samples were collected from the University of Tokyo, the Jikei University School of Medicine, St. Luke's International Hospital, National Center for Global Health, and Medicine and Tokyo Metropolitan Komagome Hospital with approval by the Ethics Committees at each site.

RNA-seq experiments

We followed the same protocol that we reported previously². Briefly, peripheral blood mononuclear cells (PBMCs) were isolated by density gradient separation with Ficoll-Paque (GE Healthcare) immediately after blood drawing. After lysis of erythrocytes, up to 26 immune cell subsets were collected with purity > 99% using a MoFlo XDP instrument (Beckman Coulter) or a 14-colour cell sorter BD FACSAria Fusion (BD Biosciences). We intended to collect a minimum of 1,000 cells (up to 5,000 cells) per subset. Libraries for RNA-seq were prepared using SMART-seq v4 Ultra Low Input RNA Kits (Takara Bio). Samples failing any of the quality control steps (RNA quality and quantity, PCR amplification, library fragment size) were eliminated from further downstream steps. Libraries were sequenced on the HiSeq 2500 Illumina platform to obtain 100-bp paired-end reads with HiSeq SBS Kit v4 (Illumina).

Mapping of the transcriptome

We followed the same protocol we reported previously². Briefly, adaptor sequences were trimmed using cutadapt (v1.16) and 3'- ends with low-quality bases (Phred quality score < 20) were trimmed

using the fastx-toolkit (v0.0.14). Reads containing more than 20% low-quality bases were removed. Subsequently, reads were aligned against the GRCh38 reference sequence using STAR (v2.5.3)⁵³ in two-pass mode with GENCODE, version 27 annotations⁵⁴. A median of 10.1 million paired fragments were uniquely mapped per sample and utilized for the subsequent analysis. Expression was quantified using HTSeq (v 0.11.2)⁵⁵.

Mapping and QC of BCR sequence

We utilized MiXCR software (version 3.0.13)⁵⁶ for BCR mapping. With FASTQ files after adapter and quality trimming, we utilized the “analyze shotgun” option with parameters “-s hsa”, “--starting-material rna” and “--receptor-type bcr”. After alignment and assembly of clonotypes based on the CDR3 sequence, the full BCR sequence was assembled with the “--contig-assembly” parameter. We set “specificMutationProbability” parameter to 2×10^{-3} . Only productive heavy-chain sequences were kept for the analysis unless specified. For all analyses, samples with more than 500 unique CDR-H3 sequences were used for the analysis. For each sample, we treated each unique BCR sequence as a single event, regardless of read depth. For mapping non-productive sequences, we raised the “specificMutationProbability” parameter to 8×10^{-3} in order to reduce the amount of productive sequences with error or mutations counted as non-productive sequences.

Mapping of whole genomic sequences

We followed the same protocol that we reported previously². Genomic DNA was isolated from peripheral blood using QIAmp DNA Blood Midi kit (Qiagen) and libraries for whole genome sequencing were prepared using TruSeq DNA PCR-Free Library prep kit (Illumina). Whole genomes were sequenced on Illumina’s HiSeq X with 151-bp pair-end reads. Data processing was based on the standardized best-practice method proposed by GATK (v 4.0.6.0)⁵⁷ with additional recalculation of

genotype quality (GQ) scores based on allele frequencies in the 1000 Genomes Project, phase 3, East Asian (EAS) population using CalculateGenotypePosteriors module from GATK. Samples with genotyping call rates < 99% were removed and multi-allelic sites were split into bi-allelic. Calls with GQ < 20 and/or DP < 5 were assigned to missing. Variants with genotyping call rates < 85% and/or HWE P-value < 1.0×10^{-6} were removed. Finally, we used BEAGLE (v 5.1)⁵⁸ to impute missing genotypes. Variants with minor allele frequency < 1% and variants on actionable 59 genes by ACMG⁵⁹ were excluded from our analysis because they were out of the scope of this research.

Principal component analysis based on VDJ gene usage

All B cell samples used in this study except those samples after belimumab treatment were utilized for PCA analysis. For each sample, each VDJ gene usage was calculated by dividing the number of clonotypes using that gene by the total number of clonotypes in that sample. We retained genes that were used more than 0.5% by 10% or more of the samples. Each gene usage was scaled to mean = 0 and variance = 1, and PCA was performed with prcomp function in R.

To project samples after belimumab treatment to the same PCA space described above, for each VDJ gene, we centered the mean and standardized the variance with regards to those calculated among all the other B cell samples above. Then, this normalized VDJ gene usage matrix and the PC loadings of each gene calculated in the above analysis were utilized for calculating PC scores for samples after belimumab treatment.

We assessed the disease effects on PC scores by linear regression analysis comparing each disease sample versus HC samples in each subset. Treatment effects on PC scores were assessed by the linear mixed model comparing samples before and after treatment, with individuals treated as random effects. The linear mixed model was fit with lme4 package.

Calculation of the Repertoire Naïveness Score

For scoring, we only included VDJ genes that were used by more than an average of 0.1% of the clonotypes in each of the 5 subsets. At first, each VDJ gene usage was scaled to mean = 0 and variance = 1 among the 5 B cell subsets of HCs. Then, the effect sizes of VDJ genes were estimated by comparing their usage between naïve B and USM B among HC samples with a linear mixed model, with individuals treated as random effects. Only genes that attained Bonferroni-adjusted p values < 0.05 in this comparison were utilized for the subsequent scoring. In addition, genes whose usage showed substantial correlation among 5 B cell subsets of HCs ($|\beta| > 0.4$ in the linear mixed model) were pruned to keep the most significantly different ones in the comparison of USM B and naïve B. As a result, 55 genes (35 V genes, 16 D genes and 4 J genes) were retained for the scoring (Supplementary table 1).

For each sample, VDJ gene usage was mean-centered and variance-standardized with regards to those calculated among the 5 B cell subsets of HCs. Then, the following formula was applied for calculating the RN score:

$$RNS_i = \sum_{k=1}^{35} \widehat{\beta}_{V_k} \times U_{V_{ik}} + \sum_{k=1}^{16} \widehat{\beta}_{D_k} \times U_{D_{ik}} + \sum_{k=1}^4 \widehat{\beta}_{J_k} \times U_{J_{ik}}$$

where $\widehat{\beta}_{v_k}$ corresponded to the effect size of the V_k gene usage comparison between USM B and naïve B among HCs, and U_{vik} corresponded to the normalized usage of the V_k gene in individual i .

Calculation of gene set enrichment score

We utilized the GSVA package⁶⁰ to calculate the gene set enrichment score for samples. After TMM normalization⁶¹ of count data, conversion to log count per million values and batch effect removal with the ComBat function from the sva package⁶², the “gsva” function was utilized for calculating the gene set enrichment score for the gene sets in Supplementary table 2. The Tph1 score was calculated using the 54 genes that were significantly upregulated in PD-1^{hi} CD4⁺ T cells compared with PD-1⁻

populations in the original article²² and normalized expression values of Th1 cells. The IFN score was calculated using 97 genes in HALLMARK_INTERFERON_ALPHA_RESPONSE gene set in MSigDB⁶³.

Association analysis with gene expression

The association of naïve B cell CDR-H3 length with gene expression in naïve B cells was assessed in each disease at first for reducing the confounding of inter-disease differences in gene expression-CDR-H3 length association. For this step, gene expression data after filtering of low expressed genes was assessed for the association with CDR-H3 length using the limma⁶⁴ package with voom transformation. Known batch effects and age were treated as covariates. Then, resultant effect sizes of each comparison and their standard deviations were utilized for meta-analysis with Metasoft (version 2.0.1) software⁶⁵.

For the assessment of association of RN score and gene expression in each immune cell subset, we also utilized limma with voom transformation. The RN score was scaled to mean = 0 and variance = 1, and known batch effects and age were treated as covariates. In this comparison, genes fulfilling FDR < 0.05 and $|\log FC| > 0.1$ were treated as significantly associated genes.

Gene set enrichment analysis

We tested the enrichment of CDR-H3 length-associated genes that passed a Bonferroni significance threshold in fixed-effect meta-analysis to hallmark gene sets by MSigDB⁶³ using the clusterProfiler package⁶⁶.

Differential usage analysis

For the assessment of disease effects on VDJ gene usage in each subset, we kept genes that were used more than 0.5% by 10% or more of the samples. For each disease, gene usage of the disease and HC

samples were scaled to mean = 0 and variance = 1 and tested for the disease effect on gene usage by linear regression with age and known batch effects as covariates.

Mediation analysis

The relationships among IFN scores, Tph1 scores and RN scores in plasmablasts were tested among SLE patients by utilizing the classical mediation analysis framework⁶⁷. The IFN score was treated as the independent variable, the Tph1 score was treated as the mediator and the RN score was treated as the outcome variable. P values were calculated via 10000-time bootstrapping using mediation package in R.

Calculation of V gene mutation frequency

For the assessment of gene mutation frequency, we quantified per-base mutation frequency in the heavy-chain V gene except for the CDR3 region, that is, in FR1, CDR1, FR2, CDR2 and FR3 regions. As MiXCR assembles the sequence of these regions after alignment and assembly of clonotypes based on CDR3 sequence, only a portion of the nucleotides is actually sequenced in these regions. We counted the number of mutations in these regions in each individual and divided it by the total number of sequenced nucleotides in these regions in the individual to infer the V gene mutation frequency.

Comparison with the data from the other cohort

The BCR repertoire sequencing data of peripheral blood mononuclear cells from healthy individual¹¹ was downloaded from the NCBI Sequencing Read Archive under BioProject number PRJNA527941.

The BCR repertoire sequencing data of sorted B cells from human tonsil¹⁹ was downloaded from ArrayExpress with the accession number E-MTAB-8999.

Gene expression data of PD-1^{hi} and PD-1⁻ T cells²² were downloaded from the ImmPort repository

with the accession number SDY939. We performed the differential expression analysis between (memoryCD4⁺PD-1^{hi}CXCR5⁺MHCII⁺ICOS⁺ + memoryCD4⁺PD-1^{hi}CXCR5⁺MHCII⁺ICOS⁺) versus memoryCD4⁺PD-1^{hi}CXCR5⁺ populations to obtain “PD-1^{hi} versus PD-1⁺ logFC”.

To validate the reproducibility of the correlation between Tph1 score and RN score in plasmablasts, we utilized peripheral blood Th1 cells and plasmablast RNA-seq data of Japanese SLE patients and HCs that we had obtained previously²⁵, which have no sample overlap with this study.

620

621 **Comparison of the frequency of IGHV4-34 clonotypes with nonmutated AVY/NHS motifs**

We counted the number of IGHV4-34 clonotypes with or without mutations in the AVY motif in the FWR1 region or the NHS motif in the CDR2 region. Only clonotypes sequenced at these positions were included in the analysis. As the number of IGHV4-34 clonotypes was not large in one sample, we aggregated the IGHV4-34⁺ clonotypes in each comparison group (e.g., SLE plasmablasts, HC plasmablasts, etc.), and compared the cumulative number of mutated and nonmutated clonotypes between groups by Fisher’s exact test.

628

629 **SHM-QTL analysis**

In each individual, all substitutions in V genes in plasmablasts were collected from “mutationsDetailed” columns for FR1, CDR1, FR2, CDR2, and FR3 regions from MiXCR output. The frequency of each of 6 nucleotide substitution pattern (i.e., C:G>A:T, C:G>T:A, C:G>G:C, T:A>C:G, T:A>G:C and T:A>A:T) was calculated in each individual. Nucleotide substitution pattern frequencies were normalized across samples using a rank based inverse normal transformation with the GenABEL package⁶⁸.

Association tests of these normalized substitution pattern frequencies and genetic variants were performed using QTLtools (v1.3.1)⁶⁹ with known batch effects, age, sex, disease and the top 2 genetic

principal components included as covariates. In total, 509 cases with whole genome information and plasmablast repertoire information were included in this analysis.

Variance of substitution patterns explained by 5 lead SHM-QTL variants was estimated by MANOVA analysis using the MVLM package. We calculated the variance of (6 -1) substitution patterns explained by full model (including the 5 lead variants, known batch effects, age and disease term) and a null model (including known batch effects, age and disease term) separately, and the difference between the two values was defined as the variance explained by 5 variants.

Data visualization and statistical test

The statistical test performed are indicated in the figure legends or Methods. Throughout the analyses, multiple test correction was performed with Benjamini-Hochberg procedure to obtain corrected q-values unless otherwise indicated. In boxplots, the center lines indicate the median, the box limits indicate the interquartile range (IQR), the whiskers reflect the maximum and minimum values no further than $1.5 \times \text{IQR}$ from the hinge and the points indicate outliers.

749 SLEDAI-2K) between SLE patients in cluster 1 and others. **h**, Skewed isotype frequencies in IMDs
750 compared to HC. In each disease (column), isotype frequency (row) was compared with HC after
751 adjusting for age and batch effects. Effect sizes of linear model comparison are plotted if the difference
752 was statistically significant ($FDR < 0.05$). **i**, Correlation between RN scores in plasmablasts and isotype
753 frequency in plasmablast. P values and r^2 values were calculated with linear regression.
754

Extended data Fig. 6: Genetic association analysis with VDJ gene usage and somatic hyper-mutation.

a, QQ-plot of V, D, and J gene usage association with genome-wide genetic variants in naïve B cells. **b**, Comparison of V gene usage-QTL effect sizes among 5 B cell subsets. For each comparison of 2 subsets, the effect sizes were compared for significantly associated V gene-top variant pairs in either of the subsets. Bars indicate 95%CI. **c**, Regional association plot of the *NUGGC* locus after conditioning on rs2305453 (left), rs13279787 (middle), and rs4732620 (right). **d**, Estimated protein structure of NUGGC using the AlphaFold2 algorithm⁷⁰. Three missense variants identified in SHM-QTL analysis are marked, two of which, Ser180 and R492, are believed to be located on the surface of the protein. **e**, Expression of *AP002852.2* in immune cells among HCs. **f**, Association of 5 independent SHM-QTL variants with 6 kinds of mutation patterns. *, $p < 5 \times 10^{-8}$.

Supplementary table legends

Table S1. Repertoire Naïveness Score calculation.

Table S2. Gene sets used for calculating gene set enrichment score.

Table S3. Abbreviations for immune cell subsets.
