Abstract

INTRODUCTION: Changes in the hippocampus are associated with both increased age and cognitive decline due to mild cognitive impairment (MCI) and Alzheimer’s disease (AD). Most studies have examined the association between hippocampal changes and episodic memory, with many reporting a relationship between hippocampal measurements and global cognition. However, these studies often find associations only in the later stages of cognitive decline. The goal of this study was to examine if hippocampal grading is associated with global cognition in cognitively normal controls (NC), early MCI (eMCI), late (lMCI), and AD, and whether such associations differ across diagnostic cohorts.

METHODS: Data from 1620 Alzheimer’s Disease Neuroimaging Initiative older adults were examined in this study (495 NC, 262 eMCI, 545 lMCI, and 318 AD). Participants were included if they completed baseline MRI scans and the Alzheimer’s disease Assessment Scale (ADAS-13) and Clinical Dementia Rating – Sum of Boxes (CDR-SB) cognitive tests. Linear regressions examined the influence of hippocampal grading on cognitive scores.

RESULTS: Lower global cognition (i.e., increased ADAS-13 scores) was associated with hippocampal grading scores in all cohorts, including normal controls. Lower global cognition (i.e., increased CDR-SB scores) was associated with hippocampal grading scores in lMCI and AD, but not in eMCI or NC groups.

DISCUSSION: These findings suggest that hippocampal grading is associated with changes in global cognition in NC, eMCI, lMCI, and AD depending on the cognitive test. Thus, hippocampal grading may be a useful measure that is sensitive to progressive changes early in the disease course.

Keywords: Older adults, Mild cognitive impairment, Alzheimer’s disease, Cognitive decline, Hippocampal grading, Cognitive functioning

1. Introduction

Increased age is associated with cognitive decline, ranging from healthy aging to mild cognitive impairment (MCI) and, in some cases, Alzheimer's disease (AD). MCI is characterized by declines in cognitive functioning that are not severe enough to impair daily activities¹. AD is characterized by progressive declines in cognitive functioning that are severe enough to impair daily activities². In both aging³ and AD⁴, neurodegeneration is an important factor that contributes to these observable cognitive deficits.

Hippocampal volume is often used as a biomarker of neurodegeneration because it is affected early in the disease course⁵, with declines in hippocampal volume occurring before observable abnormal amyloid PET⁶. It is well-established that this atrophy occurs decades before the clinical symptom presentation (i.e., measurable cognitive deficits)⁷. For that reason, examining the hippocampus and its relationship to cognitive change in healthy older adults in addition to people with MCI and AD is essential for a detailed understanding of the progressive nature of the disease.

Declines in hippocampal volume are suggested to account for episodic memory declines in aging and AD⁸. Strong associations between decreased hippocampal volume and poor episodic memory functioning support this conclusion^{9–11}. In addition to episodic memory, studies have also found a relationship between the hippocampus and global cognitive functioning^{12,13}. The correlation between hippocampal volume and global cognition has, however, remained quite moderate, $R=0.41$ ¹². When separating groups based on diagnostic status, global cognition has been correlated with decreased hippocampal volume in only AD (not MCI and NC¹⁴), and in both AD and MCI (but not NC¹⁵). Most of these studies used the mini-mental status examination (MMSE) as a measure of global cognition^{12,14,15}, which may limit the sensitivity of these associations.

Different measures of the hippocampal neurodegeneration could improve the observed relationship between the hippocampus and general cognitive functioning. Hippocampal grading, measured by the Scoring by Nonlocal Image Patch Estimator (SNIPE), has been shown to surpass hippocampal volume in predictive power^{16,17}. These researchers observed that SNIPE-based grading biomarkers are more relevant for cognitive decline prediction and conversion from MCI to AD than hippocampal volume measures¹⁶. SNIPE has a classification accuracy of 93% at distinguishing people with AD from cognitive normal (CN) individuals in the ADNI cohort¹⁸. SNIPE could also predict in cognitively normal older adults, who would progress to AD dementia within a 12y follow-up period with 72.5% accuracy¹⁷. Coupe et al. (2012b) also observed that in normal controls and people with AD, HC grading had a stronger correlation with global cognition, as measured by the MMSE, ($R=0.75$) than hippocampal volume ($R=0.58$). Associations between SNIPE hippocampal grading and cognitive declines in normal aging and early MCI have yet to be determined.

Given that the MMSE has limited value in differentiating MCI from NC¹⁹, other neuropsychological measures that are more sensitive to cognitive changes in early MCI may offer stronger associations with hippocampal volume declines. Furthermore, because hippocampal grading, as measured by SNIPE, has better predictive power than hippocampal volume, we predict that a strong association between SNIPE measures and sensitive measures of cognitive decline will be observed. The current paper was designed to determine whether measures of general cognitive functioning (i.e., the Alzheimer's Disease Assessment Scale-13, ADAS-13; Clinical Dementia Rating-sum of boxes, CDR-SB) would have a strong association with hippocampal grading in normal controls, people with MCI, and people with AD. While Coupe et al. determined that SNIPE could classify between NC and people with AD and predict

which NC may progress to AD, it remains unknown if SNIPE grading is associated with progressive changes in general cognitive functioning at different stages of decline^{16–18}. The goal of this paper was to characterize the relationship between SNIPE and cognition as measured by ADAS-13 or CDR-SB early in the disease. Although both ADAS-13 and CDR-SB are sensitive to cognitive changes in MCI and AD, the ADAS-13 has a larger range of scores (0-84) than the CDR-SB (0-18). We expect to see strong associations between the ADAS-13 in NC, MCI, and AD because of the large range in ADAS-13. In contrast, for the CDR-SB we expect to see strong associations only in the later stages of cognitive decline because NCs have a small range of scores (0-0.5). These findings would not only have implications for future development and improvement of methods to measure neurodegeneration, but also for the early detection and characterization of incipient AD.

2. Methods

2.1 Alzheimer's Disease Neuroimaging Initiative

Data used in the preparation of this article were obtained from the Alzheimer's Disease Neuroimaging Initiative (ADNI) database (adni.loni.usc.edu). The ADNI was launched in 2003 as a public-private partnership, led by Principal Investigator Michael W. Weiner, MD. The primary goal of ADNI has been to test whether serial magnetic resonance imaging (MRI), positron emission tomography (PET), other biological markers, and clinical and neuropsychological assessment can be combined to measure the progression of mild cognitive impairment (MCI) and early Alzheimer's disease (AD). Participants were selected from ADNI-1, ADNI-2, and the ADNI-GO cohorts. The study received ethical approval from the review boards of all participating institutions. Written informed consent was obtained from participants or their study partner.

2.2 Participants

Full participant inclusion/exclusion is available online at www.adni-info.org. Briefly, all participants were between 55 and 90 years old at the time of recruitment and no evidence of depression as measured by the Geriatric Depression Scale. Healthy control participants had no evidence of memory decline on the Wechsler Memory Scale and no evidence of cognitive decline on either the Mini Mental Status Examination (MMSE) or Clinical Dementia Rating (CDR). Early MCI and IMCI had to score between 24 and 30 on the MMSE, 0.5 on the CDR, and had abnormal scores on the Wechsler Memory Scale. Early MCI was differentiated from IMCI by degree of memory impairment; eMCI participants were characterized as memory impairment that is intermediate between normal controls and IMCI. AD participants had to show abnormal memory function on the Wechsler Memory Scale, an MMSE score between 20 and 26, a CDR of 0.5 or 1.0 and probable AD according to the NINCDS/ADRDA criteria.

A total of 1634 participants from three ADNI cohorts had MRI baseline scans and were thus included (ADNI-1, 787 participants; ADNI-2, 759 participants; ADNI-GO 88 participants). Inclusion criteria also included availability of baseline CDR-SB and ADAS-13 scores. Fourteen participants were excluded for not having baseline ADAS-13 scores. A total of 1620 participants were included for our study. Of these 1620 participants, 495 were cognitively normal older adults (CN), 262 were early MCI (eMCI), 545 were late MCI (IMCI), and 318 had an AD diagnosis. Table 1 summarizes demographic information for all participants.

<Insert Table 1 about here>

2.3 Structural MRI acquisition and processing

All participants were imaged using a 3T scanner with T1-weighted imaging parameters (see <http://adni.loni.usc.edu/methods/mri-tool/mri-analysis/> for the detailed MRI acquisition protocol).

Baseline scans were downloaded from the ADNI public website.

T1w scans for each participant were pre-processed through our standard pipeline including noise reduction²⁰, intensity inhomogeneity correction²¹ and intensity normalization into range [0-100]. The pre-processed images were then both linearly (9 parameters: 3 translation, 3 rotation, and 3 scaling)²² and nonlinearly (1 mm³ grid)²³ registered to the MNI-ICBM152-2009c average²⁴. The quality of the linear and nonlinear registrations was visually verified by an experienced rater (author M.D.), blinded to diagnostic group. Only seven datasets did not pass this quality control step and were discarded.

2.4 SNIPE

Scoring by Nonlocal Image Patch Estimator (SNIPE) was used to measure the extent of AD-related change in the hippocampus using the linearly registered preprocessed T1-weighted images^{16,18}. SNIPE segmentations were visually verified by an experience rater (author N.S.) The SNIPE procedure used has been previously described in detail²⁵.

2.5 Data availability statement

The data used for this analysis are available on request from the ADNI database (adni.loni.usc.edu).

2.6 Statistical Analysis

Analyses were performed using ‘R’ software version 4.0.5. Linear regression models were conducted to determine whether hippocampal grading would influence cognitive scores (CDR-SB and ADAS-13). The model examined the association between *CognitiveScore* (ADAS-13 or CDR-SB) and Hippocampal *Grading* (Right and Left). Diagnosis was the categorical variable of interest, indicated by NC, eMCI, IMCI, or AD status with NC serving as the baseline.

Grading:Diagnosis denotes an interaction term between Grading and Diagnosis, reflecting differences in the slope of Grading between the diagnostic groups. The models also included age, sex, and years of education as covariates, with the regression centered on SNIP score = 0.0 as follows:

$$\text{CognitiveScore} \sim \text{Grading}_{\text{HC}} + \text{Diagnosis} + \text{Grading:Diagnosis} + \text{Age} + \text{Sex} + \text{Education} \quad (1)$$

Correction of multiple comparisons was completed using false discovery rate (FDR); p-values are reported as raw values with significance determined by FDR correction marked in Table 2.

3. Results

Table 1 presents the demographic information for each group. There was no significant difference in age between the NC and IMCI ($t=0.9$, $p=0.4$) or between NC and AD ($t=1.36$, $p=0.2$), but the eMCI group were 3.5y younger than NC ($t=6.67$, $p<.001$). There was no significant difference in education between NC and eMCI ($t=1.83$, $p=.07$), but NC had higher education than IMCI ($t=2.58$, $p=.01$) and AD ($t=5.64$, $p<.001$). As expected, the average ADAS-13 score increased from NC to AD. Statistically significant differences were observed between each successive stage of decline were observed, NC < eMCI < IMCI < AD (NC:eMCI, $t=-8.45$, $p<.001$; eMCI:IMCI, $t=-13.89$, $p<.001$; and IMCI:AD $t=-21.43$, $p<.001$). Similarly, CDR-SB increased with NC < eMCI < IMCI < AD with statistically significant differences between each

successive group (NC:eMCI, $t=-26.47$, $p<.001$; eMCI:IMCI, $t=-5.88$, $p<.001$; and IMCI:AD $t=-27.72$, $p<.001$).

Table 2 summarizes the results of the linear regression models for both the ADAS-13 and CDR-SB analyses. Figure 1 shows a scatterplot of individual cognitive scores and hippocampal grading values for both the ADAS-13 and CDR-SB.

<Insert Table 2 and Figure 1 about here>

3.1 ADAS-13 and Hippocampal Grading

For the left hippocampus (LHC) analysis, the overall effect of LHC grading on ADAS-13 scores in the NC group was significant ($t= -3.95$, $p<.001$), demonstrating that decreases in LHC grading were associated with increases in ADAS-13 scores. In addition, all patient groups had significantly greater intercepts for ADAS-13 than the NCs, and ADAS-13 scores progressively increased (i.e., lower performance) from NC to eMCI (4.19 points more than NC, $t= 5.83$, $p<.001$), IMCI (8.13 points more than NC, $t= 15.09$, $p<.001$), and AD (17.61 points more than NC, $t= 28.80$, $p<.001$) at the model center (where SNIPE grading = 0.0). Furthermore, the interaction between LHC grading and ADAS-13 was significant for eMCI ($t= -2.22$, $p=.03$) and IMCI ($t= -2.74$, $p=.006$), and marginally significant for AD ($t= -1.85$, $p=.06$); i.e., the slopes of changes in ADAS-13 scores associated with changes in LHC grading were significantly steeper in all disease cohorts in comparison with the NCs. The slope for eMCI and IMCI was almost twice that for NC. When examining the covariates, age was not associated with change in ADAS-13 scores ($t= -1.11$, $p=.27$). Male sex was associated with almost 1 point increase in ADAS-13 scores ($t= 2.98$, $p=.003$), whereas increased education was associated with slightly lower (-0.21 points) ADAS-13 scores ($t= -4.06$, $p<.001$). Overall, 65% of the variance in ADAS-13 scores (adjusted $R^2=0.65$) can be explained by the variables included in this model.

For the right hippocampus (rHC) analysis, the overall effect of rHC grading on ADAS-13 scores in the NC group was significant ($t = -4.28, p < .001$), demonstrating that increases in ADAS-13 scores were associated with decreases in rHC grading. In addition, all patient groups had significantly greater intercepts for ADAS-13 than the NCs, and ADAS-13 scores progressively increased (i.e., lower performance) from NC to eMCI (4.10 points more than NC, $t = 5.35, p < .001$), IMCI (7.78 points more than NC, $t = 13.45, p < .001$), and AD (16.65 points more than NC, $t = 25.49, p < .001$) at the model center (where SNIPE grading = 0.0). Furthermore, the interaction between rHC grading and ADAS-13 was significant for eMCI ($t = -1.96, p = .05$), to IMCI ($t = -2.23, p = .03$), and to AD ($t = -2.51, p = .01$); i.e., the slopes of changes in ADAS-13 scores associated with changes in rHC grading were significantly steeper in all disease cohorts in comparison with the NCs. When examining the covariates, increased age was associated with slight increases in ADAS-13 scores (0.05 points, $t = 2.02, p = .04$). Male sex was associated with almost 1 point increase in ADAS-13 scores ($t = 3.00, p = .003$), whereas increased education was associated with slightly lower ADAS-13 scores (-0.24 points, $t = -4.80, p < .001$). Overall, 66% of the variance in ADAS-13 scores (adjusted $R^2 = 0.66$) can be explained by the variables included in this model.

3.2 CDR-SB and Hippocampal Grading

For the left hippocampus model, the effect of lHC grading on CDR-SB scores was not significant ($t = -0.82, p = .41$) for the NC group. All patient groups had significantly greater intercepts for CDR-SB than the NC group at model center, and CDR-SB scores progressively increased (i.e., lower performance) from NC to eMCI (1.28 points more than NC, $t = 10.96, p < .001$), to IMCI (1.58 points more than NC, $t = 18.07, p < .001$), and to AD (4.08 points more than NC, $t =$

40.90, $p < .001$). The interaction between IHC grading and CDR-SB was not significant for eMCI ($t = -0.87$, $p = .38$), but was significant for IMCI ($t = -2.43$, $p = .02$) and AD ($t = -5.28$, $p < .001$); i.e., the slopes of changes in CDR-SB scores associated with changes in HC grading were significantly steeper slopes in the later disease cohorts (IMCI & AD) compared to NCs. When examining the covariates, increased age was associated with increases in CDR-SB scores (0.01 points, $t = 2.49$, $p = .01$), male sex was not associated with change in CDR-SB scores ($t = -0.71$, $p = .48$), and education was only marginally associated with lower CDR-SB scores (-0.02 points, $t = -1.85$, $p = .06$). Overall, 73% of the variance in CDR-SB scores (adjusted $R^2 = 0.73$) can be explained by the variables included in this model.

For the right hippocampus model, the effect of rHC grading on CDR-SB scores was not significant ($t = -0.76$, $p = .45$) for the NC group. All patient groups had significantly greater intercepts for CDR-SB than the NCs, and CDR-SB scores progressively increased (i.e., lower performance) from NC to eMCI (1.30 points over NC, $t = 10.25$, $p < .001$), to IMCI (1.58 points over NC $t = 16.50$, $p < .001$, and to AD (4.06 points more than NC, $t = 37.48$, $p < .001$). The interaction between rHC grading and CDR-SB was not significant for eMCI ($t = -0.94$, $p = .35$), but was significant for IMCI ($t = -2.22$, $p = .03$), and AD ($t = -4.49$, $p < .001$); i.e., the slopes of changes in CDR-SB scores associated with changes in HC grading were significantly different (steeper slopes) in the later disease cohorts (IMCI & AD) in contrast with the NCs. When examining the covariates, increased age was associated with slight increases in CDR-SB scores (0.01 points, $t = 2.53$, $p = .01$), male sex was not associated with change in CDR-SB scores ($t = -0.63$, $p = .53$), whereas increased education was associated with slightly lower CDR-SB scores (0.02 points, $t = -2.36$, $p = .02$). Overall, 73% of the variance in CDR-SB scores (adjusted $R^2 = 0.73$) can be explained by the variables included in this model.

4. Discussion

The current study used SNIPE to measure hippocampal grading in NC, eMCI, IMCI, and AD, and compared these grading scores to global cognitive functioning as measured by the ADAS-13 and CDR-SB. In contrast to NCs, both IMCI and AD required less hippocampal change to have decreased ADAS-13 and CDR-SB scores (reflected by their significantly steeper slopes in the regression models). The eMCI group required less hippocampal change compared to normal controls to have decreases in only the ADAS-13; whereas this group's association between hippocampal change and CDR-SB scores did not differ from NC. These findings indicate a relationship between lower cognitive scores in eMCI, IMCI, and AD with decreases in hippocampal grading.

Previous associations between global cognition in people with MCI and hippocampal volume have been mixed. Vipin et al. (2018) reported no relationship between hippocampal volume and global cognition in MCI¹⁴, while Peng et al. (2014) found an association between hippocampal volume and global cognition in people with MCI¹⁵. These conflicting findings could be associated with the sensitivity of the MMSE to early cognitive decline as well as the use of hippocampal volume.

In the current study, we observed an association between hippocampal grading and global cognition, as measured by the ADAS-13 score in all groups - NC, eMCI, IMCI, and AD. This finding suggests that SNIPE hippocampal grading is sensitive to global cognitive declines due to aging (in the NC group), early in the disease process (i.e., eMCI), and to the progressive changes that occur later in AD-related pathology. Taken together with the previous research on SNIPE

¹⁶⁻¹⁸, these results suggest that this method could be useful in the future prediction of cognitive decline and diagnostic status early in the disease trajectory.

When examining global cognition using the CDR-SB, associations between hippocampal grading were only observed in the IMCI and AD groups. As expected, CDR-SB scores were low for the normal controls (i.e., either 0 or 0.5), resulting in a flat slope for this group. As can be seen in Figure 1, the eMCI group has a much smaller range and median (0-4; median=1) CDR-SB values than both IMCI (0-5.5; median=1.5) and AD (1-10; median=5.5). The lack of association with the eMCI group may thus be related to the limited range of CDR-SB scores in people with eMCI. The relationship became stronger with IMCI and AD, showing that the relationship between hippocampal grading and CDR-SB is stronger in those with more severe declines. Consistent with previous studies, associations between CDR-SB and hippocampal grading were also stronger in the left, rather than right hippocampus ^{15,26}.

While both ADAS-13 and CDR-SB were associated with hippocampal grading for both IMCI and AD, only the ADAS-13 was associated with hippocampal grading in eMCI and NC. CDR-SB was more sensitive (than ADAS-13) to changes in hippocampal grading that occur later in the disease progression, as reflected by the interaction with grading and IMCI and AD. These findings suggest that the relationship between grading and cognitive score can be sensitive to different stages of disease progression.

Regarding the normal controls, these findings suggest they would require much more hippocampal change (as measured by grading) for the same amount of cognitive decline to occur compared to the patient groups. For example, HC changes may affect the grading score, but compensation through cognitive reserve or plasticity may limit declines in cognitive functioning measured by the cognitive tests. Further research is needed to elucidate this issue.

The present study has a few limitations that should be investigated in future research. All participants in our sample had a high education, which may limit the interpretation and generalizability of the results to other populations. To improve our sample size, participants were included from ADNI-1, ADNI -2, and ADNI -GO. Therefore, we could not differentiate between cognitively normal participants with and without subjective cognitive decline (SCD) because a question to measure this construct was only introduced for ADNI-2. Recent research has observed that hippocampal volume decreases are associated with episodic memory performance in people with SCD ²⁷. Thus, future research should determine whether SNIPE grading is sensitive to hippocampal changes and global cognitive functioning in people with SCD. These findings should be replicated in longitudinal data to determine whether grading scores are predictive of clinical cognitive change at an individual level.

Conclusion

The findings from this study indicate a strong association between hippocampal grading changes and global cognition. Importantly, the relationships were observed not only late in the disease course (AD and IMCI) but also earlier in the course of the disease during eMCI. Hippocampal grading may be a useful measure that is sensitive to progressive changes in global cognition as measured by the ADAS-13 starting in the preclinical phase and CDR-SB starting in the prodromal phase of AD. Future work is needed to determine if HC grading is predictive and associated with longitudinal changes in cognition at an individual level.

Table 1: Demographic information for cognitively normal, early and late MCI, and AD participants.

	NC n=495	eMCI n= 262	IMCI n= 545	AD n= 318
Age	74.34 ± 5.76	70.84 ± 7.39	73.97 ± 7.57	75.03 ± 7.70
Education	16.34 ± 2.72	15.97 ± 2.64	15.89 ± 2.91	15.17 ± 3.02
Female Sex	260 (53%)	115 (44%)	209 (38%)	143 (45%)
ADAS-13	9.23 ± 4.32	12.57 ± 5.56	18.72 ± 6.52	29.95 ± 7.91
CDR-SB	0.04 ± 0.14	1.29 ± 0.76	1.65 ± 0.93	4.43 ± 1.64

Notes. Values are expressed as mean ± standard deviant, or number (percentage %). Female Sex is represented as total number of sample and percentage of sample. NC = cognitively normal controls. eMCI = early mild cognitive impairment. IMCI = late mild cognitive impairment. AD = Alzheimer's disease. ADAS-13 = Alzheimer's Disease Assessment Scale–Cognitive Subscale. CDRSB = Clinical Dementia Rating Scale – Sum of Boxes

Table 2: Linear regression model results showing effects of grading on cognitive scores

	ADAS-13:Left HC	ADAS-13:Right HC	CDR-SB:Left HC	CDR-SB:Right HC

Adjusted R-squared	0.65	0.66	0.73	0.73

Note: Bolded values are statistically significant. * Represents results that were significant after false discovery rate correction

for multiple comparisons. eMCI = early mild cognitive impairment; IMCI= late mild cognitive impairment; AD= Alzheimer's

Disease; HC = hippocampus; ADAS-13 = Alzheimer's Disease Assessment Scale-13; CDR-SB = Clinical Dementia Rating Scale –

Sum of Boxes.

Figure 1: Scatterplots of Cognitive Score by Hippocampal Grading

All images show individual points grouped by color as well as the regression line for each group. Dark blue lines = Cognitive normal (CN); Light green lines = early mild cognitive impairment (eMCI); orange lines = late mild cognitive impairment (LMCI); and red lines = Alzheimer's disease (AD). ADAS-13 = Alzheimer's Disease Assessment Scale–Cognitive Subscale. CDR-SB = Clinical Dementia Rating Scale – Sum of Boxes. Negative grading scores indicate greater similarity to the Alzheimer's anatomy, while positive scores indicate similarity to healthy controls. From left to right, the x-axis starts with A&B) Higher ADAS-13 scores were associated with decreases in hippocampal grading in all groups. C&D) Higher CDR-SB scores were associated with decreases in hippocampal grading in all groups except CN.
