Abstract

Background: Natural and vaccine-induced immunity play an important role in controlling the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic. Understanding humoral immunity to SARS-CoV-2 is of great importance for evaluating vaccine performance and inform public health decisions.

Objective: We aimed to evaluate the level of IgG antibodies against SARS-CoV-2 and their persistence post infection or post-vaccination.

Methods: A serological analysis (Immunoassay) to investigate the level of anti-spike IgG antibody responses following infection with SARS-CoV-2 or immunization with the first or second dose of the AstraZeneca, Sputnik, Sinovac and Sinopharm vaccines was performed.

Results: A total of 9460 seropositive individuals were recruited. The mean levels of anti-spike IgG antibodies were higher in vaccinated participants with prior COVID-19 infections than in individuals without prior infection. Decline for IgG antibodies were faster in vaccinated individuals without previous COVID-19 infection compared to those with previous COVID-19 infection.

Conclusion: A single dose of the vaccine is likely to provide greater protection against SARS-CoV-2 infection in subjects with prior SARS-CoV-2 infection, than in SARS-CoV-2-naïve individuals. In addition, previous COVID-19 infection elicited robust and sustained levels of SARS-CoV-2 antibodies in vaccinated individuals.

Keywords: COVID-19 vaccines, humoral immunity, SARS-CoV-2, antibody titers, spike protein

Introduction

SARS-CoV-2, the virus that causes COVID-19 has infected more than 304 million people around the world as of January 9, 2022, causing more than 5.4 million deaths¹. Both vaccination and herd immunity are important for controlling pandemics². However, the only way to reach herd immunity is by vaccination rather than by natural infection³, which makes vaccination crucial². Vaccines stimulate different parts of the immune system, including humoral immunity. Therefore, production of neutralizing antibodies (IgG, IgM) is an indicator of vaccine efficacy. This is also observed after COVID-19 infection⁵. SARS-CoV-2 causes either symptomatic or asymptomatic infection⁶ and induces the production of neutralizing antibodies in most patients⁷ within two weeks after the onset of symptoms⁸. The duration of the humoral immune response and its protective efficacy are still unclear. Several studies have measured the levels of neutralizing antibodies induced by vaccination against SARS-CoV-2, which may play an important role in controlling viral infection⁹. Detection of SARS-CoV-2 antibodies indicates current or past infection¹⁰. However, the durability of antibody responses and their stability over time remain debatable. Regardless of natural infection or post vaccination. Some studies reported that antibodies did not decline within four months after infection¹¹. Others showed rapid decline of antibody levels, their late appearance, and even seronegativity¹². Some reports estimated that antibodies and memory cells against SARS-CoV-2 persist for at least 4–8 months¹⁴. Another study reported that IgG levels persist for at least nine months after exposure to the virus¹⁶. So far, the immunity obtained from vaccination is not lifelong or even very long-lasting, but it seems to control the infection to some extent².

In Libya, since the vaccine campaign began in April 2021, four types of vaccines have been administered. According to the National Centre for Disease Control in Libya, more than one million individuals have been vaccinated with the first dose and a total 816,927 second doses have been administered (National Center for Diseases Control, n.d.). Evaluation of immunity after vaccination is important for determining the protection provided by the vaccine. Notably, breakthrough infections may reflect poor post vaccination response. This study evaluated the levels of IgG antibodies against SARS-CoV-2 and their persistence after infection and/or post-vaccination.

Material and methods

Participants and study design

We investigated anti-spike IgG antibody responses following infection with SARS-CoV-2 and/or immunization with the first dose or with two doses of the vaccines in use in Libya. The study was conducted on the Libyan general population in several coastal cities. The study started with initial recruitment of 15,000 participants between August 15th and December 31st 2021. The participants were recruited from people visiting healthcare centers and employees in state institutions. The inclusion criterion was age > 18 years and exclusion criteria were pregnancy, transfusion with blood or plasma during the three months preceding the study, immunosuppressive therapy, recent chemotherapy, autoimmune diseases, and renal dialysis. Blood samples of 3 ml were obtained by venipuncture using Vacutainer tubes. The samples were coded, and serum was separated and stored at 20°C until analyzed within 48 hours. The Bioethics Committee at the Biotechnology Research Center in Tripoli (Ref No. approved the study BEC-BTRC 8-2020). The study protocol was compatible with the World Medical Association Declaration of Helsinki (Ethical Principles for Medical Research Involving Human Subjects). All participants provided written informed consent to participate. Those who agreed to participate were given an information sheet detailing the study aim, pledging anonymity of their information, and explaining that they have the right to withdraw from the study at any time. A self-administered questionnaire was used to collect data on sex, age, the type of vaccines received, the date(s) of vaccination, side effects, severity of symptoms, previous Covid-19 infection, and whether the infection (if there was one) was before or after receiving the vaccine. Information on past medical history and influenza vaccination status were also noted.

Detection of SARS-CoV-2 specific serum antibodies

The Beckman Coulter Access Anti-SARS-CoV-2 IgG assay was used on a UniCel DxI 600 Access Immunoassay System to detect anti-SARS-CoV-2 antibodies according to the manufacturer's instructions (Beckman Coulter, Germany). A sample was considered reactive (positive) for anti-S IgG if the result was ≥ 10 AU/ml.

Statistical analysis

A web application was developed with PHP, MySQL and JavaScript specifically for electronically collecting survey data and initial statistical analysis. However, the statistical analysis was performed using Microsoft Excel and GraphPad Prism version 9.3. The descriptive statistics included mean, standard deviation and percentages. The differences between mean values were compared by the unpaired Student's t-test. P values < 0.05 were considered statistically significant.

Results:

Participant selection and characteristics of study group

The study was conducted on 9460 individuals, including both symptomatic and asymptomatic recoveries, as well as persons vaccinated with the first dose or with both doses of the vaccine (Figure 1).

Figure 1. Flowchart showing recruitment and participant selection.

Males represented 54.2% of the study sample. The ages of the participants ranged from < 35 to 90 years, and their age distribution is shown in figure 2.

Figure 2. Age distribution of the participants

Overall view of vaccinations and seropositivity

Of the 9640 participants, 6328 had been vaccinated (65.6%). Of the 3132 unvaccinated individuals who were seropositive, 1200 did not report a previous infection, pointing to a rate of asymptomatic COVID-19 of 38.3% in this group. The most frequently used vaccines were Sputnik ($n = 4156$, 65.7%) followed by AstraZeneca ($n = 1065$, 16.7%). Only 17.5% of the participants had been vaccinated with 579/6328 (Table 1). Of the 6328 vaccinated participants, 68.8% were seropositive. The rate of positivity was lowest for the Sinovac and Sinopharm vaccines (52.2% and 52.4%, respectively) and considerably higher for the AstraZeneca and Sputnik vaccines (73.8% and 71.9%) (Table 1).

Table 1. Distribution of vaccinated participants by sex, vaccine type, and IgG seropositivity

Vaccine	n			Seropositive	
	Females	Males	Total	n	%
Sputnik	1874	2282	4156	2988	71.9
AstraZeneca	479	586	1065	786	73.8
Sinopharm	237	257	494	259	52.4
Sinovac	306	307	613	320	52.2
All vaccines	2896	3432	6328	4353	68.8

Analysis of seropositivity by age, vaccination status, and prior infection status

The distribution of seropositivity rates by age group, prior infection status and vaccination status is shown in table 2. In general, seropositivity rates increased with age. Notably, 100% of the participants who had been administered one dose, whether previously infected or not, were seropositive, with the exception of those below 35 years of age and had not been previously infected, among whom seropositivity rate was 87.9% (Table 2). A dip in positivity rate in the eldest age groups was also noticed in fully vaccinated individuals regardless of infection status (Table 2).

Table 2. Seropositive individuals by age group, vaccination status and prior infection status

	≤ 35 years		36-45 years		46-55 years		55-65 years		> 65 years	
	p=0.0001		p<0.0001		p=0.0003		p<0.0001		p=0.0002	
	N	%	N	%	N	%	N	%	N	%
1. Unvaccinated with prior infection	386	77.0	320	96.0	307	93.0	147	95.0	40	88.8
2. Unvaccinated seropositive (asymptomatic)	597	62.8	484	74.3	536	82.0	206	92.0	102	78.0
3. Vaccinated with first dose with prior infection	358	100	582	100	419	100	308	100	383	100
4. Vaccinated with first dose seropositive (asymptomatic)	585	87.9	637	100	678	100	443	100	354	100
5. Fully vaccinated with prior infection	150	100	149	94.2	164	100	56	97.0	227	93.8
6. Fully vaccinated seropositive (asymptomatic)	210	72.8	129	79.3	184	82.8	126	86.9	188	90.9

Overall, the seropositivity rate was higher among unvaccinated individuals who reported prior infection (convalescent) than those who did not (asymptomatic) (Table 2). In unvaccinated convalescent individuals, seropositivity was similar in the five age groups, ranging from 77% (≤ 35 years) to 96% (36-45 years). In contrast, seropositivity among asymptomatic unvaccinated individuals increased with age from 62.8% (< 35 years) to 92% (55-65 years), after which there was a dip to 78% (Table 2).

Trajectories of IgG levels in previously infected individuals who received one vaccine dose

From week 1 after vaccination, the mean titers of IgG against the spike protein increased for all vaccines but were considerably higher for the Astra-Zeneca and Sputnik vaccines, which, by week 11, reached 169.2 and 142.0 AU/ml, than for Sinopharm and Sinovac (92.4 and 99.3 AU/ml). However, while the levels against Sputnik and AstraZeneca peaked on week 7 and then started a gradual decline, the IgG levels against Sinovac and Sinopharm continued to rise until week 15, when the levels against the four vaccines became very similar, ranging from 113.6 AU/ml (Sinopharm) to 123.8 AU/m (Sputnik) (Figure 2). Thereafter, the rate of decline was more notable for AstraZeneca and Sinopharm. From week 19 to week 21, anti-Sputnik and anti-Sinovac IgG levels were the highest.

Figure 3. Average anti-spike IgG titers after first vaccination dose in previously infected participants

In seropositive participants without evidence of prior infection, post-vaccine antibody responses showed that positive anti-spike IgG results increased over the 3–4 weeks after the first vaccination in case of Sputnik, AstraZeneca and Sinovac respectively (Figure 3). In terms of Sinopharm, the titration began raised over the 5 week. The higher average of titration IgG were observed in Sputnik in week 12 (108.36 AU/ml. P value <0.005) while in case of AstraZeneca subjects maximum antibody titration was seen in week 10 (132.67 AU/ml. P < 0.005). The higher titration of seropositive value were (93.7 and 91.05 AU/ml. P < 0.005) in Sinopharm and Sinovac respectively.

Figure 4. Average anti-spike IgG titers after first vaccination dose in seropositive participants who never had COVID-19 symptoms

In fully vaccinated respondents, the average titers of anti-spike IgG in participants who had received AstraZeneca or Sputnik vaccine were 257 AU/ml and 221 AU/ml, respectively (p value < 0.005), which is considerably higher than in those who had received only the first dose with or without prior infection (Figure 4). Similar observation were seen in Sinopharm and Sinovac as compared with patients administrated first dose showed in figure 2,3.

Figure 5. Trajectory of average of anti-spike IgG titers of fully vaccinated individuals (two doses) with or without previous infection.

Discussion

The main finding of the study is that among the unvaccinated seropositive individuals, 61.7% had experienced symptoms of the disease while 38.3% had not. Plebani et al. reported that a strong positive association is being increasingly found between antibodies titers and disease severity, which distinguishes asymptomatic from symptomatic patients¹⁸. Our results confirm previous findings that prior infection is associated with higher titration of SARS-CoV-2-specific serum-IgG antibodies¹⁹. Of 9460 participants, 3132 (32%) were unvaccinated yet seropositive and therefore had been exposed to SARS-Cov2 infection. 1932 participants were asymptomatic. Furthermore, that asymptomatic and mildly ill participants seem to produced low levels of antibody-mediated immunity has important implications for understanding herd immunity¹². In addition, subjects individuals vaccinated with first dose with prior COVID-19 infection (natural immunity) significantly higher titration IgG than first dose-vaccinated individuals without prior infection (acquired immunity)²⁰. Further, the current results support the observation that infected vaccinated participants showed higher mean titration than uninfected vaccinated first dose only²¹. Moreover, our finding states that in SARS-CoV-2 naturally infected individuals a single vaccine dose seems sufficient to reach immunity. We also found that a single-dose of “Sputnik Light” vaccine formed a faster humoral immune response in seropositive participants had previous infection, same finding published by Tikhvatulin et al 2021²². Tretyn et al status that, primary humoral immunity, one of the indicators of which is the presence of IgG antibodies, appeared 2 weeks post administrating the mRNA vaccine^{23 24}. Same result obtained in our study, IgG triggered since 2 weeks particularly in patients received first dose without prior infection in all vaccines type involved in our study. Based on these results, one can assume that a prior SARS-CoV-2 infection triggered the immune system to a very strong response to a single dose of the vaccine. The first dose, given in to individuals whose immune systems previously stimulated by the natural infection, had a similar effect when given as a second “booster” dose. Our observations are consistent with the studies of Voysey et al. who published data demonstrated that in subjects who immunized after natural COVID-19 infection, antibody responses after the first dose of

AstraZeneca vaccine were higher than in participants without prior infection ²⁵. In light with the increased demand and shortage of vaccine supply, this finding would support implementing a strategy of a single vaccine dose for individuals who were previously infected by SARS-CoV-2. Furthermore, respondents fully-vaccinated individuals with or without previous COVID-19 infection showed highly titration value in terms of AstraZeneca and sputnik 239 AU/ml and 221 AU/ml in week 17 respectively. IgG against COVID-19 exist detected until 24 week, which consider long duration as compared with subjects, received on dose. Two vaccine doses achieved high responses across all age groups, and particularly increased r people seroconverting to similar levels to those receiving one dose after prior infection ²⁶. Wei et al confirmed that, significantly increased seropositivity and antibody levels in participants received two vaccine dose ²⁷. The decline in IgG levels over time was expected since this occurs for all vaccines types involving in the current study. The serological analysis in this study was performed an average of five months post vaccination. This finding agreed with previous published data showing that antibodies detected for several months after vaccination ²⁸. Additionally, in vaccinated individuals, IgG levels were maintained for longer times in those who were previously infected than in those who were not ^{21,29}.

Interestingly, this type of response is present whether individuals developed a symptomatic COVID-19 disease. These observations are in line with the hypothesis that the first vaccine dose serves as a boost in naturally infected individuals ²⁹. Our findings have important implications for vaccination policy. In light of the growing demand and shortage of vaccine production, this finding would support implementing a strategy of a single vaccine dose for persons who were previously infected by SARS-CoV-2. Although we are expected that the continuing vaccination campaign should provide some control of disease, spread and reduce the degree of mortality and morbidity rate among population, but will not prevent the spread of infection. The findings of the current study have some limitations. First, the study did not include children and immunocompromised adults. Furthermore, most fully vaccinated participants did not receive the second dose on schedule, which could reflect on the accuracy of results.

Conclusion

In summary, detectable SARS-CoV-2, anti-spike IgG levels among unvaccinated individuals due to previous infection either if the symptomatic and asymptomatic showed the good immunity status for

individuals. Vaccination with prior COVID-19 infection demonstrated higher IgG titration than vaccination without prior infection. The persistence of spike antigen-specific serum IgG following vaccination is hopefully a positive indicator of effective long-lived immunity, and clinical indicator of vaccine efficacy. Our results suggest that even greater efforts should be made to immunize more individual, particularly people without prior COVID-19 infection. However, further investigations are needed to estimate the maintenance of these immune responses and the potential need for booster doses.

Author contributions

Study Conception and design: AE, FE, IA and ZA. YL, SD, WH, HE, NG, FM, FS, RT, ME and MA performed the antibody titer tests. RA, ST and FE analyzed the data. MJ and FE wrote the introduction, YA wrote the methods, FE wrote the results and discussion. AZ, FE IA finalized the manuscript. All authors had full access to all the data in the study, reviewed the final manuscript, and approved its submission for publication.
