Summary

Between February 2019 and March 2021, 388 dried blood spot samples were obtained from 257 children <30 months of age who were part of a longitudinal maternal/infant cohort in Haiti. Among the children followed, 16.7% became seropositive; sampling date was the only covariate associated with the hazard of seroconversion.
While there have been a number of population-based serologic studies that have assessed rates of SARS-CoV-2 infection, work to date has largely been among adults in the developed world.\(^1,2\)

Of the 968 studies included in a recent meta-analysis, the majority (77%) of papers retained for analysis were from high income countries, which tended to have lower seroprevalence than low-to middle-income countries (LMIC).\(^1\) Most of the papers that have been published, irrespective of income,\(^3,4\) have focused on school-age or adult populations, with very limited data available on infections among the youngest age groups. However, it has also been observed that young infants have SARS-CoV-2 viral loads higher than those seen in other age groups, suggesting that they can play a critical role in transmission within a household setting.\(^5\) Given these circumstances, it becomes extremely important to understand the rate of infection and immune responses amongst infants in LMIC to facilitate development of appropriate surveillance and intervention strategies.

The first case of COVID-19 in Haiti was identified on March 19, 2020. As part of an international multi-site study to assess the impact of viral infection on pregnancy outcome (the ZIKAction project),\(^6\) our group monitored a maternal and child cohort in the Gressier region of Haiti, with dried blood spot (DBS) samples collected from infants between birth and 30 months of age between February 2019 and March 2021. Serendipitously, this time period included the first reported Haitian COVID-19 cases and the peaks of the first and second Haitian COVID-19 “waves” (Figure 1). We used these data and samples to assess serological responses to SARS-CoV-2 among study infants during the first year of the pandemic in Haiti. The predominant SARS-CoV-2 lineage circulating in Haiti during the study was B.1, with smaller numbers of cases in the B1.478 and B1.1 lineages.\(^7\)
Methods

This study was conducted under review of the University of Florida (UF) IRB and the Haitian Comite National de Bioethique of the Ministere De La Sante Publique Et De La Population. Mothers in the study were recruited at the time of their first antenatal visit; basic demographic, epidemiologic, and clinical data were obtained; and efforts were made to follow all infants born to enrolled mothers, with visits scheduled at 0, 4, 12, and 18-30 months of age. During visits, infants were screened for developmental delays, and DBS samples were collected by heel-stick. Mothers were also asked to report illness in their infants since the infant was last seen by study staff. Travel within Haiti was severely limited during the study period because of substantial political unrest and the COVID epidemic. Many mothers were also hesitant about allowing a heel-stick for blood collection. Because of this, it was not possible to obtain samples from all infants at all scheduled time points.

Detailed laboratory methods are provided in Supplemental Materials. In brief, a single 6mm biopsy punch was used to capture the area covered with each blood spot. Because the blood spots varied in size and intensity, the amount of total protein in each sample was determined by using a Bradford protein microassay. A research ELISA, adapted from a previously published protocol, was developed and used to target the SARS-CoV-2 Receptor Binding Domain (RBD).

We estimated that with 50 samples collected before the pandemic and 50 after, we had 80% power to detect a difference in seroprevalence assuming 15% of babies would be seropositive after the beginning of the pandemic and 0% before (with 95% confidence). We fit regression
models to average ODs to determine factors associated with larger OD values. A mixture model was fit to the average OD’s across all samples, assuming that observations came from two distributions, those that had not been infected and those that had in the past. A threshold in OD value was identified from the mixture model that indicated a 95% probability of belonging to the distribution associated with higher values (OD>0.21). This threshold was used to define individual measurements as indicating seropositivity. Interval censored survival analysis was used to investigate the association of the hazard of SARS-CoV-2 seropositivity possible risk factors.

Results
We obtained 388 samples from 257 children; numbers of samples by year and time point are shown in Supplemental Table 1. Longitudinal samples were obtained from 107 of these children consisting of two or more samples: this includes 84 infants for whom two samples were available, 22 with three samples, and one for whom samples were available for all four time points. The average protein concentration for all samples was 5,194 ug/mL with 18 measuring below 100 ug/mL and the highest measuring 13,209 ug/mL. There were no differences in mean protein levels when analyzed for age or year.

Using the dataset of all samples (388), a spline investigating the relationship between time of sampling and OD indicated that average ODs increased ~0.200 in value at 400 days past January 1, 2019 or approximately March 2020 (Supplemental Figure 1). Increases in ODs that occurred in 2020 and 2021 reflected the timing of waves of reported for SARS-CoV-2 cases and deaths in Haiti over the same time periods (Figure 1). No anti-SARS-CoV-2 IgG responses above the
predicted cut-off occurred before July, 2020 and no infant was seropositive at birth. Forty-three
(16.7% [95% CI 12.7%-21.8%]) of 257 unique children tested seropositive at some point during
the study.

We conducted a survival analysis to account for differing amounts of person time for each
individual and over time (Figure 2, Supplemental Figure 2). We fit piecewise constant hazard
survival models to estimate the hazard of anti-SARS-CoV-2 seropositivity over time in our study
population. Hazards estimated for intervals before and after March 1, 2020 found that hazards
were significantly larger in the later interval (Hazard ratio of 39.1 95% CI 13.1, 2.8e7). Age of
child, mother’s age, educational attainment, marital status, urban/rural status and parity of birth
were not associated with the hazard of infection. Trends in OD were similar across age groups
(Supplemental Figure 3).

Twenty-one of the consecutively tested children tested above the cut-off in 2020 and 2021, with
seven testing above the cut-off on two of the samples. One child (of 8 total) who had a sample
collected after an initial seropositive sample became seronegative upon follow up. Only limited
data were available on clinical illnesses experienced by children during the study. However, no
child was diagnosed at a medical facility as having COVID-19, based either on clinical
presentation or laboratory testing, and mothers did not spontaneously report occurrence of more
severe illnesses in their infants that might have been consistent with COVID-19.
Comment

The overall seropositivity rate of 16.7% among our infant cohort was lower than the 39% seroprevalence previously reported by our group for adult populations in Haiti during a comparable time period. This may be a reflection of lower exposure of neonates and very young children to the general population. The adult data were collected from predominantly urban populations in Port-au-Prince. Given that studies in Peru and South Africa have demonstrated higher seroprevalence rates in more densely populated urban areas as compared with rural areas, caution should be used in directly comparing the data from our infants (the majority of whom came from a rural origin) with these adult data.

In work performed in middle and upper income countries, SARS-CoV-2 seropositivity in children generally identified as below the age of five has been highly variable, from less than 1% in German and Switzerland to 6% in Spain after during the first surge of the pandemic. Several U.S. studies examined antibody prevalence in residual blood samples of children during the late spring and early fall of 2020, with seroprevalence rates of 9.5 - 16.3%. Recently, a cross sectional investigation of SARS in Virginia reported 8.5% seropositivity in a study of 1,038 children; seroprevalence was highest (13.7%) in children in the 0-5 year age group. Our data are consistent with the observation that rates of seropositivity are higher in LMIC settings and underscore the widespread distribution of infection in very young children in these areas, with no risk factors identified other than occurrence in the midst of an epidemic wave.

In keeping with data showing little evidence of serious clinical illness in infected infants, we did not obtain a history of a serious preceding illness among our seropositive infants, nor were any
of the children in the study formally diagnosed as having COVID-19. However, our data
document that infections do occur in infants and elicit an immune response. These studies were
conducted at a time when B.1 lineage strains were predominant in Haiti and need to be repeated
with the successive waves of Gamma, Delta, and Omicron strains which have occurred;\textsuperscript{7} the
health impact of these later lineages also remains to be determined. However, given that infants
have been shown to have high SARS-CoV-2 viral loads,\textsuperscript{5} our findings underscore the potential
importance of very young children in facilitating virus transmission within LMIC households
and communities, and the need to consider these youngest members of society in developing
models and prevention strategies for COVID-19.
