ABSTRACT

Background: Norovirus and sapovirus are important causes of childhood acute gastroenteritis (AGE).
Breastfeeding prevents AGE generally; however, it is unknown if breastfeeding prevents AGE caused specifically by norovirus and sapovirus.

Methods: We investigated the association between breastfeeding and norovirus or sapovirus AGE episodes in a birth cohort. Weekly data on breastfeeding and AGE episodes were captured during the first year of life. Stools were collected from children with AGE and tested by RT-qPCR for norovirus and sapovirus. Time-dependent Cox models estimated associations between weekly breastfeeding and time to first norovirus or sapovirus AGE.

Findings: From June 2017 to July 2018, 444 newborns were enrolled in the study. In the first year of life, 69 and 34 children experienced a norovirus and a sapovirus episode, respectively. Exclusive breastfeeding lasted a median of 2 weeks, and any breastfeeding lasted a median of 42 weeks. Breastfeeding in the last week did not prevent norovirus (HR: 1.09, 95% CI: 0.62, 1.92) or sapovirus (HR: 1.00, 95% CI: 0.82, 1.21) AGE in a given week, adjusting for household sanitation, consumption of high-risk foods, and mother’s and child’s histo-blood group phenotypes. Maternal secretor-positive phenotype was protective against norovirus AGE, whereas child’s secretor-positive phenotype was a risk factor for norovirus AGE.

Interpretation: Exclusive breastfeeding in this population was short-lived, and no conclusions could be drawn about its potential to prevent norovirus or sapovirus AGE. Non-exclusive breastfeeding did not prevent norovirus or sapovirus AGE in the first year of life. However, maternal secretor-positive phenotype was associated with a reduced hazard of norovirus AGE.
WHAT IS KNOWN

- Breastfeeding prevents acute gastroenteritis (AGE) in nursing infants.
- It is unknown if breastfeeding prevents AGE caused by norovirus or sapovirus, which are leading causes of childhood AGE worldwide.
- Host genetic factors can influence AGE risk, and the mediating effects of breastfeeding are unclear.

WHAT IS NEW

- Exclusive breastfeeding was rare, and breastfeeding did not prevent norovirus (hazard ratio 1.09, 95% CI: 0.62, 1.92) or sapovirus (hazard ratio 1.00, 95% CI: 0.82, 1.21) AGE.
- Secretor-positive phenotype of the child and the mother may be more important than breastfeeding in determining norovirus and sapovirus AGE risk in this setting.

KEYWORDS

Norovirus, sapovirus, breastfeeding, acute gastroenteritis, diarrhea, Nicaragua, infants, histo-blood group antigens.
INTRODUCTION

Acute gastroenteritis (AGE) is a common cause of morbidity and mortality worldwide, with the greatest burden among children in developing countries. Human caliciviruses, which include norovirus and sapoviruses, are a leading cause of AGE in both outbreak and endemic settings. Although people of all ages are susceptible to norovirus infections, the highest morbidity and mortality is among young children and the elderly. Sapovirus is increasingly recognized as an important etiology of AGE among young children, with the prevalence ranging from 5 – 17% depending upon the country, age group studied, and laboratory methods used. In the MAL-ED multi-site cohort study, sapovirus has been recognized as the second highest attributable incidence of AGE in children under 24 months of age.

The protective effect of breastfeeding against childhood AGE is well established. However, few studies have investigated the association between breastfeeding and specific causes of AGE, such as from norovirus and sapovirus infections. The current evidence from the published literature shows mixed results for norovirus and sapovirus; some studies have shown that breastfeeding is associated with a decreased odds of infection, while others have shown no reduction. Moreover, when breastfeeding was assessed in these studies, there were inconsistencies and lack of clarity in how breastfeeding frequency and exclusivity were treated as analytic variables.

Along with breastfeeding, child and mother’s secretor phenotype affects individuals’ susceptibility to enteric infections. More specifically, the mother’s secretor phenotype can alter breastmilk composition, and the child’s secretor phenotype can increase or decrease the risk for diarrheal diseases of specific etiology, including norovirus genogroups. However, limited evidence exists on the association between detailed breastfeeding history, child and mother’s histo-blood group antigens (HBGAs) phenotypes and the risk of norovirus or sapovirus AGE.

Our research investigated the protective association between breastfeeding and incidence of first norovirus and sapovirus AGE episodes during the first 12 months of life in a longitudinal birth cohort.
study (SAGE) in León, Nicaragua. The SAGE birth cohort employs a rigorous follow-up approach and a platform to study the weekly impact of breastfeeding on the incidence and severity of norovirus and sapovirus infections. A secondary goal of the study was to understand the combined impacts of child and maternal genetic factors on norovirus and sapovirus AGE risk, and whether these influence the benefits of breastfeeding on AGE prevention.

METHODS

Study design

The Sapovirus Associated GastroEnteritis (SAGE) study is a population-based birth cohort in León, Nicaragua that aims to investigate the natural history, immunity, and transmission patterns of sapovirus and 13 other enteric pathogens associated with pediatric gastroenteritis. The target sample size to detect a three-fold risk of sapovirus infection with 90% power among children with an infected household member was 400. During the recruitment period between June 2017 and July 2018, 991 expected births were identified from exhaustive pregnancy registries maintained by public health centers, which were highly representative of the full population of León. A total of 742 mothers were contact in their homes, of whom 585 were eligible to participate and 444 agreed to participate (recruitment rate: 76%). Newborns were enrolled between birth and 14 days of age and were followed weekly for up to 36 months. Ten fieldworkers underwent training in administering surveys and collecting biological samples, then conducted in-person household visits to collect baseline data on sociodemographic factors; weekly data on breastfeeding behavior, supplemental feeding, and incidence of AGE episodes; and monthly data on environmental and behavioral risk factors for AGE. Fieldworkers participated in biweekly meetings to review study protocols and update trainings.

Measures
The main outcome was the first episode of AGE in which norovirus or sapovirus was detected in the stool. AGE surveillance occurred weekly, and an AGE episode was characterized by diarrhea, defined as ≥3 stools that were loose or looser than normal in a 24-hour period, including notable changes to the stool, such as presence of blood or excessive liquid; and/or vomiting. This analysis was restricted to the first detected episode of norovirus or sapovirus. Breastfeeding practice was ascertained using a weekly questionnaire administered to the mothers. Children for whom the answer to the question “Did you breastfeed your child yesterday?” was “Yes” were considered breastfed. The child was considered to be exclusively breastfed until the first week the mother answered “Yes” to question “In the past week, has your child received any food, formula, or liquids, including water or tea or liquid in a bottle, in addition to breast milk?”; the child was considered non-exclusively breastfed thereafter. Children were considered to have “any breastfeeding” if they received either exclusive or mixed breastfeeding at any point in the first 12 months of the study.

Severity of norovirus and sapovirus episodes were summarized on a scale of 0-15 based on the presence of the following symptoms and treatment-seeking behaviors: diarrhea lasting 1-2 days = 1 point, 3-4 days = 2 points, 5+ days = 3 points; vomiting lasting 1-2 days = 1 point, 3-4 days = 2 points, 5+ days = 3 points (0 points if no vomiting); maximum of 4-5 stools per day = 1 point, 6-7 stools = 2 points, 8+ stools = 3 points (0 points if no diarrhea); presence of fever = 3 points; intravenous fluid received for dehydration = 3 points. This severity score was based on the method described by Lee, et al, though we did not collect temperature when fever was reported.19

Risk factors for AGE included socioeconomic status, nutrition, and secretor and Lewis phenotype. The presence of a toilet in the household at enrollment was a surrogate measure for household income. On a monthly basis, mothers were asked if their child ate any food that is associated with increased AGE risk, including seafood (any kind), raw fruits or vegetables (any kind), or any food outside of the home. Considering the increasing evidence of the importance of host genetic factors in modifying susceptibility to infections, including in a prior study conducted in the same birth cohort,17 we adjusted...
for the child’s secretor and Lewis phenotypes. Due to the additional potential for mother’s HBGAs phenotypes to be associated with AGE risk, we also adjusted for mother’s secretor and Lewis phenotypes.

**Sample collection and laboratory methods**

Stool samples were collected from children with AGE within 10 days of the onset of symptoms. Specimens were collected from a plastic container or a soiled diaper retrieved from the household within two hours of defecation and transported at 4°C to the Microbiology Department of UNAN-León for analysis. A 10% (wt/vol) suspension of stool was prepared using phosphate-buffered saline (pH=7.2). The samples were tested for norovirus and sapovirus within 24 hours of collection.

Viral RNA extraction was performed on collected stool samples using the QIAamp Viral RNA Mini Kit (Qiagen, Hilden, Germany), according to manufacturer’s instructions. Extracted viral RNA from stool suspensions was analyzed by reverse transcriptase quantitative polymerase chain reaction (RT-qPCR) for norovirus as previously described. Sapovirus infection was detected by RT-qPCR in stools as previously described. Briefly, RT-qPCR was performed with the AgPath-ID OneStep RT-qPCR Kit (Thermo Fisher Scientific, Waltham, MA, USA) using the ABI 7500 Real-Time PCR System. A sample was considered positive for norovirus or sapovirus if the Ct value was ≤ 35. HBGA phenotypes were determined by analysis of saliva samples collected from cohort children at 6 months of age. If the result was indeterminate, we tested the samples collected at 12 or 24 months of age. Saliva samples from mothers were collected at the end of the study and tested for HBGAs phenotypes.

**Data analysis**

Breastfeeding exclusivity and duration, based on weekly household surveys, and incidence of norovirus and sapovirus AGE episodes were summarized using descriptive statistics. Crude and adjusted hazard ratios (HR) for the association between breastfeeding and norovirus and sapovirus AGE were estimated using time-dependent Cox proportional hazard models. Breastfeeding behavior was measured
weekly based on mothers’ reports. All children were followed from baseline until 12 months of age, until
they experienced a norovirus or sapovirus AGE episode, or until they were lost to follow-up. This
analysis is restricted to the first episode reported for each child. Hazard ratios were adjusted for
potentially confounding factors, including socioeconomic factors, nutritional factors, and the child’s and
mother’s secretor and Lewis phenotypes (positive or negative). Data were analyzed using SAS version 9.4
(Cary, North Carolina) and Stata 14 (College Station, Texas).

This study was approved by Institutional Review Boards at the University of North Carolina
School of Medicine (IRB #: 20-0698), the National Autonomous University of Nicaragua (UNAN)-León
(IRB #: 00003342) and CDC (Research determination: 0900f3eb81c526a7).

RESULTS

Study population characteristics

Of 444 children recruited in the study, 443 (99.8%) completed at least one weekly follow-up visit
and were included in the analysis. By the 12-month visit, 375 children (84.6%) remained enrolled in the
study and 68 had withdrawn. Mothers of all 443 children reported having breastfed their children at least
once in the first 12 months of life. Half of the children received exclusive breastfeeding at some point
during the study (Table 1). The median duration of exclusive breastfeeding was 2 weeks (IQR: 1-4
weeks), and the median duration of any breastfeeding was 43 weeks (IQR: 18-49 weeks) (Table 1). Sixty-
nine children (15.6%) experienced an AGE episode associated with norovirus genogroups GI and GII,
and 34 children (7.8%) experienced a sapovirus AGE episode in the first year of life. The median age at
first norovirus or sapovirus infection was approximately 8 months (Figure 1).

Severity of norovirus and sapovirus infections
Norovirus and sapovirus episodes were of moderate severity, having severity scores of 5 and 4.5, respectively, on a scale of 0-15. Four of the 69 norovirus AGE episodes (5.8%) and three of the 34 sapovirus AGE episodes were associated with diarrhea lasting more than 14 days. Only norovirus episodes were associated with hospitalization (n=4), three of which required intravenous rehydration.

Maternal and child histo-blood group antigen profiles

Secretor phenotype was available for 312 mothers, 244 (78.5%) of whom were secretors, and for 442 children, 395 (89.4%) of whom were secretors (Table 2). Most norovirus episodes occurred among secretor positive (98.6%) and Lewis positive (85.5%) children, as did most of the 34 sapovirus episodes (88.2% each for secretor and Lewis positive) (Table 2). Approximately three-quarters of norovirus and sapovirus cases occurred among children with secretor-positive or Lewis-positive mothers.

Relative hazard of norovirus and sapovirus AGE by breastfeeding frequency

The model adjusted for socioeconomic factors, nutrition factors, and child’s and mother’s genetic phenotypes showed no protective association of breastfeeding against norovirus episodes (HR: 1.09, 95% CI: 0.62, 1.92) (Table 3). In this model, child secretor-positive phenotype was the strongest risk factor for norovirus AGE (HR: 11.02, 95% CI: 1.50, 80.80), whereas mother secretor-positive phenotype was the strongest protective factor for norovirus AGE (HR: 0.55, 95% CI: 0.29, 1.05). Lewis-positive phenotype of the child or the mother was not significantly associated with protection against norovirus AGE. For sapovirus, adjusted estimates showed no protective association of breastfeeding (HR: 1.00, 95% CI: 0.82, 1.21). For both norovirus and sapovirus, having a toilet in the household tended to confer some protection against clinical disease, as did consumption of high-risk foods (seafood, raw fruits or vegetables) and food outside the household (Table 3).

Our study sample had a higher proportion of children who were secretor-positive compared to mothers, which was unexpected given that this salivary phenotype is inherited as a dominant Mendelian trait. When the analysis was restricted to mothers of secretor-positive children, the protective association
between mother secretor-positive phenotype showed slightly greater protection against norovirus AGE (HR: 0.52, 95% CI: 0.27, 1.00).

In a post-hoc analysis, we estimated the association between breastfeeding and severity of AGE episodes among children who experienced symptomatic norovirus (n=69) and sapovirus (n=34) infections. We used the median severity score (norovirus: 5; sapovirus: 4.5) as the cutoff for severe versus non-severe episodes. Because of the reduced number of outcomes in this analysis, the HR estimates were highly imprecise and did not suggest a definitive association between breastfeeding and AGE severity for norovirus (adjusted HR: 1.56, 95% CI: 0.65, 3.73) or sapovirus (adjusted HR: 1.46, 95% HR: 0.27, 7.85).

**DISCUSSION**

Breastfeeding was predominantly non-exclusive among the mother-infant pairs in this Nicaraguan birth cohort and was not associated with protection against norovirus and sapovirus AGE episodes. Child’s secretor-positive phenotype was a strong risk factor for norovirus AGE, whereas mother’s secretor-positive phenotype tended to be protective against norovirus AGE in their children. These influences of secretor status were not observed for sapovirus AGE.

The most recent World Health Organization (WHO) guidelines for infant and young child feeding recommend exclusive breastfeeding for the first six months of life and list protection against gastrointestinal infections among one of the chief benefits of exclusive breastfeeding. Most mothers in the cohort (98%) reported ever breastfeeding at enrollment. However, the duration of exclusive breastfeeding in our study was short, which prevented us from arriving at definitive conclusions regarding the association between exclusive breastfeeding and norovirus and sapovirus AGE. According to UNICEF, many Latin American countries, including Nicaragua, have suboptimal breastfeeding practices, with only 32% of children younger than six months being exclusively breastfed. A prior study of breastfeeding practices in León found only 12.7% exclusive breastfeeding for six months, and indicated
that travel time to a health center greater than one hour was associated with exclusive breastfeeding in the first six months of life.\textsuperscript{23} In León, most women have access to a health post in their neighborhood, suggesting that exclusive breastfeeding is more common among women living in remote or rural areas.

Children experienced their first norovirus and sapovirus episodes at approximately 8 months of age, long after most mothers had stopped breastfeeding exclusively and began introducing supplementary foods, suggesting that some maternally-acquired immunity prevented infections in early infancy.

However, Nicaraguan women are guaranteed eight weeks of paid maternity leave after delivery, which may preclude exclusive breastfeeding for the recommended six months as mothers return to the work force.\textsuperscript{24} Cultural and social factors may also impact breastfeeding practices among young mothers in urban areas, as they are uncomfortable breastfeeding in public or believe that prolonged breastfeeding will negatively affect breast shape or volume. Given the limited duration of exclusive breastfeeding in our population (median 2 weeks), future studies should be conducted in a different population where exclusive breastfeeding is practiced more widely and for longer duration, or as part of a clinical trial that provided lactation support personnel who would constantly advise and encourage new mothers enrolled in the study to continue exclusive breastfeeding. These studies would allow us to better understand the association between norovirus and sapovirus AGE and exclusive breastfeeding.

We were also surprised that consumption of high-risk foods and eating food outside of the home were associated with protection against sapovirus AGE. We found that consumption of seafood and fresh fruits and vegetables were positively associated with having piped water in the home, which is a marker of higher socioeconomic status. If nutritional practices were associated with other factors that were protective against sapovirus AGE, the relationship between high-risk foods and sapovirus AGE could be confounded.

Our study, like others, shows that a higher risk of norovirus AGE in the first year of life is associated with child’s secretor-positive phenotype but not with Lewis-positive phenotype.\textsuperscript{16,17,25} However, an important finding in our study is the protective association of mother’s secretor-positive
phenotype on norovirus AGE, unlike other studies which have found fewer norovirus infections among
children of non-secretor mothers, an enhanced protection against all-cause diarrhea in breastfed children
of non-secretor mothers, or no effect on norovirus infections. The protective effect of mother’s
secretor-positive phenotype noted in our study might be explained by higher concentrations of specific
human milk oligosaccharides (HMO) and HBGAs in breastmilk, which in turn can inhibit norovirus
binding to the infant’s intestinal epithelium. It is also possible that breastmilk from secretor-positive
mothers contains higher titers of norovirus-specific IgA that can neutralize norovirus in the infant’s
gut. Another possible explanation is that secretor-positive mothers might transfer higher titers of
norovirus-specific IgG antibodies with broader specificity to their children through the placenta, and such
maternal antibodies contribute to limited infections very early in life; the protective effect of maternal
antibodies on norovirus disease have not been extensively explored. Future studies should further
investigate these associations to better understand the role of maternal secretor status on risk of norovirus
and sapovirus AGE.

A limitation of this study was the limited duration of exclusive breastfeeding, which precluded
making valid inferences regarding the association between exclusive breastfeeding and norovirus or
sapovirus AGE. Furthermore, 30% of mothers had missing data for the secretor and Lewis phenotypes,
and we did not impute missing data for this covariate. Thus, these mothers were excluded from the
adjusted analyses and the statistical power was decreased. In addition, our study may be subject to social
desirability bias, as mothers may be more likely to report exclusive breastfeeding in accordance with
Ministry of Health recommendations. We did not assess routinely-collected stools for asymptomatic
calicivirus infections, nor did we test all AGE stools for a wide panel of enteric infections. Thus, we
cannot conclude that symptoms were caused by norovirus and sapovirus infections specifically. It is
possible that breastfeeding is associated with protection against other enteric pathogens that we did not
assess in the current analysis.
Despite these limitations, our study is one of the few studies to focus on breastfeeding as a primary exposure to understand its association with norovirus and sapovirus AGE. In contrast to previous studies that explored breastfeeding as a fixed variable, our study provides more granular insight into breastfeeding treated as a weekly varying exposure, an approach that closely mirrors actual practices. Our findings reinforce the importance of continuing to study the protective benefits of breastfeeding and the mechanisms by which breastfeeding can prevent early childhood infections. Our findings also suggest that breastfeeding, especially non-exclusive breastfeeding, may not be sufficient to reduce AGE associated with all enteric pathogens, and that combinations of interventions to reduce childhood AGE are warranted.

ACKNOWLEDGMENTS

We greatly appreciate the participation of the parents of the children contributing to the SAGE cohort, and recognize the immense efforts of the laboratory and fieldwork team: Merling Balmaceda, Vanessa Bolaños, Nancy Corea, Jhosselyng Delgado, Marvel Fuentes, Yadira Hernández, Llurvin Madríz, Patricia Mendez, Yuvielka Martínez, María Mendoza, Ruth Neira, Xiomara Obando, Verónica Pravia, Yorling Picado, Aura Scott, and Mileydis Soto. The authors are grateful for support from the local Ministry of Health office in León, and we thank the personnel from the Perla María Norori Health Center for their administrative support in recruitment of study participants. The findings and conclusions in this article are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention.
