The Effects of Maternal Obesity on Some Obstetric Features: A Comparative and Descriptive Study

Abstract

Background: The worldwide increase in obesity triggers the increase in the incidence of obesity during pregnancy. In this study, it was aimed to examine the effects of maternal obesity on some obstetric features.

Methods: This study was conducted in a tertiary hospital with a comparative group, cross-sectional and descriptive design. The data of the study were collected with a Data Collection Form created by the researchers. Descriptive statistics, Pearson’s chi-squared test, independent-samples t-test, and multinomial regression analysis were used to analyze the data.

Results: In this study, women were divided into two groups, namely the obese group (BMI>29.9 kg/m²) and the normal weight group (BMI 18.5-24.9 kg/m²). There was no significant difference between the groups in terms of their height, education level, employment status, income level, and place of residence (p>0.05). It was determined that the obese group had higher rates of multiparity, postmature deliveries, and fetal distress developing in their babies on labor (p<0.05). There was no significant difference between the groups in terms of their modes of delivery, onset of labor, and the requirement of interventions during the second stage of the labor (p>0.05). In the logistic regression analysis, maternal obesity was found to increase the rates of multiparity by 1.758 times (1.038-2.978 CI, p=0.036), post-maturity by 5.902 times (1.283-27.164 CI, p=0.023), and moderate postpartum hemorrhage by 2.286 times (1.433-3.646 CI, p=0.001).
Conclusion: It is important that women who have obesity problems in the preconception period are counseled to help them reach a normal BMI. Health care professionals should advise women on healthy nutrition and weight control during both the pregnancy and postpartum periods.

Keywords: maternal; obesity; weight; body mass index; postpartum

Introduction

Obesity is a common, serious, and costly disease [1]. The term obesity is used for greater weight gain than is generally considered healthy for a given height [2,3]. A body mass index (BMI) of 30 kg/m\(^2\) or above in pregnancy at the time of first prenatal follow-up is defined as maternal obesity [4]. BMI is used to determine overweight or obesity [5]. BMI is a person's weight (in kg) divided by their height in meters squared (BMI=Kg/m\(^2\)). WHO defines women who have a BMI of 25 kg/m\(^2\) or above as overweight, and women with a BMI of 30 kg/ m\(^2\) or above are defined as obese.

Globally, there are more obese people than underweight people. This occurs in all regions except sub-Saharan Africa and some parts of Asia. In WHO regions, the rate of BMI\(\geq\)30 kg/m\(^2\) was determined as 29% in the Americas, 25.3% in Europe, 19.5% in the Middle East, and 4.6% in South-East Asia. The proportion of women with BMI values equal to or greater than 30 kg/m\(^2\) was reported to be 31.7% in the USA, 27.1% in Europe, 24.3% in the Middle East, and 6% in South-East Asia [6]. In the 2018 report of the Turkey Demographic and Health Survey, it was specified that 29% of women aged 15-49 were overweight, and 30% were obese [7]. In parallel with the increase in obesity in the general population, the incidence of obesity in pregnancy increases worldwide [8]. A study which examined the most recent version of the four national population guidelines reported an increase in the rates of obesity in pregnant women in parallel with the increase in the general population [9]. The Royal College of Obstetricians and
Gynaecologists reported that 21.3% of the UK population is obese, and less than half (47.3%) of pregnant women have a normal BMI [10]. In a study conducted in Australia, it was found that 55% of pregnant women were overweight or obese, and 43.6% gained more weight than recommended during pregnancy [11].

Obesity in pregnancy is considered a high-risk condition as it is associated with many complications [12]. Health risks for obese pregnant women were reported in a systematic review. These included gestational diabetes, gestational hypertension, preeclampsia, antenatal anxiety, and mental health problems including depression and postpartum depression, increased rates of cesarean section, instrumental delivery, and increased rates of post-cesarean section surgical site infections [13]. It is known that obese pregnant women who gain less than 5 kg of weight during pregnancy have a decrease in the incidence of risky conditions such as hypertension, eclampsia, gestational diabetes, and cesarean section. It was observed that there was an increase in maternal risks in obese pregnant women who gained weight by over 9 kg during pregnancy [14]. The relevant literature shows that maternal obesity negatively affects maternal health during the pregnancy, childbirth, and postpartum periods. In this context, it was aimed in this study to determine the effects of maternal obesity on some obstetric features.

Based on the literature, the study sought answers to two research questions:

1. What are the effects of maternal obesity on the obstetric characteristics of women?
2. What are the relationships between maternal obesity and the obstetric characteristics of women?

**Materials and methods**

**Study design and setting**

This study was conducted in a tertiary hospital with a comparative group, cross-sectional and
The data of the study were obtained between 15 June and 31 December 2021. The research was carried out in one of the most populated districts of Turkey's 3rd largest city. There are approximately 5400 births per year in this district.

The population of the study consisted of women who gave birth in the hospital where the study was conducted, who had a BMI in the range of 18.5-24.9 kg/m² before pregnancy and those in the early postpartum period with a BMI higher than 29.9 kg/m². The minimum sample size of the study was calculated by power analysis. According to the power analysis, a margin of error (α) of 0.05, 95% power to represent the population, and with an effect size of 0.448, the required sample size was determined as 262 women, including 131 women with obesity problems and 131 women with normal weight [15]. When the effect size was taken as 0.383, the error margin (α) was 0.05, and power to represent the population (confidence interval) was 95%, the required sample size was calculated as 298 women, including 149 obese women and 149 normal-weight women [16]. A total of 320 women, 160 women in each group (case and control groups), were included in the study by considering the possibility of loss of data during the conduct of the study. The study was completed with 310 women. 155 women with a BMI of >29.9 kg/m² and 155 with a BMI in the range of 18.5-24.9 kg/m² were included in the study. In the selection of the sample, the purposive sampling method was used. In the post hoc power analysis of the study, the 1-β value was calculated as 0.99.

Purposeful sampling technique was used in this study to reach obese women in the puerperal period. Not using the randomization method increased the risk of bias. However, the study was descriptive and included a specific group (maternal obese women).

Participants

Pregnant women who volunteered to participate in the study, lived in Burdur province, used
herbal products in their current pregnancy, were not diagnosed with a psychological disease and not receiving any medications, were older than 18 years, were literate in Turkish, and completely responded to the data collection forms were included in the study. Pregnant women who did not use herbal products were excluded from the study. Also, pregnant women who did not meet the inclusion criteria were excluded from the study.

Those who gave birth in the hospital, were over the age of 18, could read, write, and speak Turkish, and didn’t have any chronic diseases (e.g., diabetes, hypertension, thyroid diseases), had pre-pregnancy weight values that could be accessed from their medical records (at the family health center or hospital), agree to participate in the study, a pre-pregnancy BMI value of 18.5-24.9 kg/m$^2$ or >29.9 kg/m$^2$ depending on their allocation group, were in the first 24 hours of the postpartum period, and did not have physical or mental health problems that would prevent their participation in the study were included in the study. Women who had a BMI range of 26.0-29.9 kg/m$^2$ before pregnancy and those who wanted to leave the study at any stage of the study were excluded.

**Data Collection Tool**

The data were obtained with the "Data Collection Form" developed by the researchers in line with the relevant literature.

*Data Collection Form* consisted of questions about the sociodemographic characteristics (age, current body weight, pre-pregnancy body weight, total weight gained during pregnancy, height, pre-pregnancy BMI, postpartum BMI, postpartum waist circumference, education, family type, employment status, income level, place of residence) and obstetric characteristics (parity, time of childbirth, mode of delivery, labor induction status, status of having an intervention in the second stage of birth, status of fetal distress development in childbirth, status of hemorrhage in
the emergency puerperium period) of the participants [13,17-18].

**Data collection procedure**

According to the classification used in the studies conducted by WHO (2021), CDC (2019), and NICE (2014), women with a BMI of 30 kg/m$^2$ or greater are obese, and those with a BMI in the range of 18.5-24.9 kg/m$^2$ accepted to have a normal weight [2,5-6]. The women included in the study were divided into two groups as obese group and normal weight group. The purpose of the study was explained to the women included in the study and the consent form was signed.

The researcher obtained the data by face-to-face interview technique. The physical examinations and measurements of the women who were mobilized within the first 24 hours postpartum were performed, and the necessary information was recorded in the forms. Additionally, the information given by the participants was confirmed by examining their hospital record files. Missing data were completed based on information obtained from these files and from the family health centers where the participants were registered. Filling out the data collection forms, making the measurements, and conducting the physical examinations took approximately 20-25 minutes for each participant.

Opinions and suggestions of five midwife with Ph.D were taken about the data collection form developed by the researchers to ensure its validity and applicability. After the final of the data collection form was given, a pretest was applied to 10 pregnant women (5 experimental and 5 control groups). Pre-tested pregnant women were excluded from the study. While collecting the data of the study, participants were excluded from the study because 3 women refused to participate in the study (MO:2, NW:1), 3 participants were under the age of 18 (MO:1, NW:2), 2 participants were illiterate (MO:1, NW:1), 1 participant could not speak Turkish (NW:1), 1 participant did not want to continue the study (MO:1) (Figure 1).
Data analysis

The analysis of the data obtained in the study was conducted with appropriate statistical methods in the IBM SPSS Statistics 22 (SPSS Inc., Chicago, IL) program. Descriptive statistics (mean, standard deviation, frequency, percentage, and distribution range) were used to analyze the main information. The normality of the distribution of the data was tested by skewness values, kurtosis values (-1.5-+1.5), and the Kolmogorov-Smirnov test. Parametric tests were used to analyze the data, as the data were normally distributed. The independent-samples t-test, Pearson’s chi-squared test, and multinomial regression analysis methods were used in the analyses. \( p < .05 \) was considered significant in the interpretations of the results of the analyses.

Ethical aspect of the study

The approval of an Ethics Committee (Decision No: 2021/08-19), the permission of the institution, and permissions for use of the scales were obtained to conduct the study. The purpose of the study was verbally explained to the potential participants, and an informed consent form was signed by those who agreed to participate in the study. The principles of the Declaration of Helsinki (revised in Brazil 2013) were followed in the research protocol. The study data were stored within the scope of personal data protection principles. Due to anonymity and confidentiality, no personally identifiable data such as name and address were obtained. No women were harmed as a result of this study.

Results

In this study, the participants were divided into two groups: maternally obese (MO: BMI >29.9 kg/m\(^2\)) and normal weight (NW: BMI 18.5-25.9 kg/m\(^2\)) groups. The study was completed with
a total of 310 puerperium participants, 155 of whom were maternal obese and 155 with normal weight (Figure 1). Therefore, their pre-pregnancy weight (MO: 83.50±9.87 kg vs NW: 56.38±7.15 kg), current weight (MO: 91.14±11.30 kg vs NW: 67.33±8.97 kg), total weight gained during pregnancy (MO: 11.08±4.75 kg vs NW: 12.33±6.03 kg), BMI pre-pregnancy (MO: 32.53±2.77 kg/m² vs NW: 21.85±2.06 kg/m²), postpartum BMI (MO: 35.72±3.57 kg/m² vs NW: 25.96±3.14 kg/m²), and postpartum waist circumference (MO: 107.06±9.28 cm vs NW: 90.97±8.66 cm) variables were significantly different (p<0.05). Additionally, there was a significant difference between the groups in terms of their mean ages (MO: 28.78±6.14 vs NW: 26.89±6.00) and family types (nuclear family; MO: 69.0% vs NW: 82.6%) (p<0.05). The mean heights of the participants (MO: 159.95±4.42 cm vs NW: 160.92±5.08 cm), their education levels (primary education; ML: 43.9% vs NW: 45.2%), and employment statuses (not working; ML: 93.5% vs NW: 92.3%) were not significantly different (p>0.05). There was also no significant difference between the groups in terms of their income levels (income less than expenditures; MO: 69.0% vs NW: 69.7%) or places of residence (province; MO: 71.0% vs NW: 78.7%) (p>0.05) (Table 1).

No interventional application was made to women during the data collection process. In addition, no direction was given that could lead to negative attitude and behavior changes. The study did not have any side effects or adverse effects on participants.

**Discussion**

In this study, the effects of maternal obesity on some obstetric characteristics of women were examined. It was determined that the majority of the obese participants were multiparous and gave birth at term. Additionally, postterm delivery and moderate postpartum hemorrhage were observed more frequently in the obese group. Maternal obesity was determined to increase the rates of multiparity (1.758 times), post-maturity (5.902 times), and moderate postpartum hemorrhage (2.286 times). Fetal distress at birth developed only in the infants of the obese participants. There was no significant difference between the groups in terms of their modes of delivery, labor induction statuses, and statuses of undergoing intervention in the second stage of labor.

Studies have shown multiparity as one of the causes of weight gain in women of reproductive
age. In most of such studies, a positive association between parity and weight gain or BMI has been reported [19-20]. In one study, it was determined that overweight women were more likely to be unable to lose the weight they gained during pregnancy than underweight women were [21]. Gestational weight gain was also found to negatively affect the return to pre-pregnancy weight and postpartum weight loss [19]. Parity was positively associated with long-term obesity risk among Chinese women [20]. A positive correlation was also observed between numbers of deliveries and obesity in Iranian women. In particular, it was shown that high parity was associated with BMI [22]. In this case, it can be stated that multiparous women have a higher risk of obesity.

Pregnancies lasting longer than 40 weeks were associated with maternal obesity and especially morbid obesity ($OR$: 2.32, 95% CI: 1.73–3.12) [23]. Similarly, post-maturity was observed in obese women in a retrospective study in Russia [24]. Studies have reported higher rates of post-maturity in obese people [18, 25]. In one study, it was stated that the incidence of preterm childbirth was lower in obese women compared to non-obese women. In a systematic review, the risk of preterm birth was not found to be significantly different in infants whose mothers were overweight or obese [26]. In two cohort studies, however, the risk of preterm childbirth was found to be higher in overweight and obese women than in normal-weight women [27-28]. It was observed that the sample sizes of the aforementioned studies were quite large. These differences may be due to the differences among their sample sizes. Based on the information obtained, no clear conclusion could be reached about the relationship between preterm childbirth and obesity.

The likelihood of postpartum hemorrhage is moderately increased in obese women compared to women with normal BMI [29]. In a previous study, it was found that obesity did not increase the occurrence of severe hemorrhage [30]. In a study conducted in the Netherlands, obesity was
not found to be associated with major obstetric hemorrhage[31]. In another study, it was reported that obesity did not affect postpartum hemorrhage status [32]. NICE (2017) emphasized that a BMI of 35 kg/m\(^2\) or above increases the risk of postpartum hemorrhage [33]. Meta-analysis studies have confirmed that a BMI of 25.00 kg/m\(^2\) or above increases the risk of postpartum hemorrhage [17, 34-35]. Similar to studies with high levels of evidence, postpartum hemorrhage was observed in the obese participants in this study, and it can be argued that obesity increases the risk of hemorrhage.

In a systematic review, infants whose mothers were overweight or obese were found to be at a higher risk of stillbirth than infants whose mothers were of normal weight [26]. Similarly, another study revealed that overweight or obese women have higher rates of stillbirth and neonatal death than those of normal weight [36]. Intrauterine hypoxia was observed in the infants of women with 3rd obesity [24]. The infants of obese women have a higher risk of developing fetal distress compared to the infants of normal-weight women (\(OR:2.67, 95\% CI:1.18–3.58\)) [37]. The results of other studies in the relevant literature and those of this study suggested the infants of obese women have a higher risk of developing fetal distress during birth.

In a previous study, there was no significant difference between obese women and normal-weight women in terms of their modes of delivery [30]. In a study conducted in China, it was stated that the rates of cesarean section deliveries were very high, and the increased prevalence of obesity in women was among the reasons that could explain the high cesarean rates [38]. In another study, increased BMI was associated with the likelihood of cesarean section. Overweight and obese women were found to have a 1.58 to 2.75-fold greater risk of cesarean section deliveries [39]. In this study, no significant difference was found between the normal weight and obese groups in terms of their modes of delivery. In our country, Cesarean section...
is perceived as a painless mode of delivery and is generally preferred by individuals with high socio-economic status. Since the institution where this study was conducted is a public hospital, usually individuals with low socio-economic status present to the institution. Moreover, cesarean delivery in the institution is performed based on necessity, not preference. There may not have been a difference between the groups due to the low socio-economic levels of the women included in the study and the fact that cesarean section was not optional.

One study showed that the rates of spontaneous labor initiation were higher than predicted in obese pregnant women. However, the authors determined that the rate of spontaneous labor was lower in obese women compared to normal-weight women. Moreover, in the same study, it was observed that the need for labor induction was more prevalent in obese women compared to normal-weight women [32]. In another study, BMI was found to not affect the rates of deliveries requiring intervention [39]. It was reported that as BMI increased, the rate of spontaneous labor decreased [40]. In a meta-analysis study, it was found that the incidence of vaginal childbirth requiring intervention was higher in obese women.

**Strengths and Limitations**

There were some limitations in this study. The fact that the patient rooms in the maternity ward of the hospital where this study was conducted have 4 or more beds, and there are baby-sized beds next to the mothers' beds may have caused the space to narrow and the room to be crowded and noisy. For this reason, there was difficulty in creating sufficient space and establishing communication while measurements were being made. Additionally, due to the COVID-19 pandemic that emerged during the data collection process, the access of health workers working in external units to the gynecology service was restricted, the families were more anxious, and the unit’s employees preferred their procedures to be performed with less contact. Women in
the mildly obese category were not included in this study. Thus, the results might not apply to women who are mildly obese.

The strength of this study is that there a strong correlation was found between maternal obesity and some complications in childbirth and the postpartum period. The significance of these findings can be examined from different perspectives. The results indicate the need for advice and counseling programs for obese women to lose weight before pregnancy. They also point to the classification of obese pregnancies as high-risk pregnancies and the provision of appropriate antenatal care to these women. Additionally, they suggest that widespread obesity among women of reproductive age is associated with several health risks for women later in life.

**Conclusion**

In this study, it was determined that the majority of the participants in the maternally obese group were multiparous and gave birth at term. However, postterm birth and moderate postpartum hemorrhage were found to be more common in the obese group. Fetal distress in childbirth developed only in the infants of the obese women. It is important to provide counseling or referral to a nutrition and dietetics specialist so that women who have obesity problems in the preconception period can reach normal BMI values. As the number of deliveries increases, the risk of obesity increases, and midwives should provide counseling to women about healthy nutrition and weight control during both the pregnancy and postpartum periods.

Starting from the pre-pregnancy period until the end of the postpartum period, midwives have an important role in providing the necessary attention and care to mothers with obesity problems and regulating healthy lifestyle habits and behaviors. To prevent obesity, which is a health problem of our age, and the complications it causes and develop potential interventions, it is recommended to conduct extensive research on factors related to maternal obesity and make
sense of the associated mechanisms.
