## 29 Abstract

30 Introduction: Welding fumes contain a mixture of metals and are an epitype for 31 environmental metal-related neurotoxicity. Past studies of welders focused largely on basal ganglia 32 regions and their association with parkinsonism. This study evaluated medial temporal lobe (MTL) 33 structures that play a key role in Alzheimer's disease-like pathology.

Methods: Exposure history and whole blood metal levels were obtained from subjects with/without a history of welding (42 welders; 31 controls). MTL regions of interest (ROI) (hippocampus, entorhinal and parahippocampal cortices) were assessed by morphologic (volume and cortical thickness) and diffusion tensor imaging [mean (MD), axial (AD), radial diffusivity (RD) and fractional anisotropy (FA)] metrics. Cognition was evaluated using standard neuropsychological tests.

40 **Results:** Welders had higher blood levels of Cu, Fe, K, Mn, Pb, Se, and Zn (p's<0.026) 41 than controls. Welders had higher MD, AD, and RD in all MTL ROIs (p's<0.040) and lower FA 42 in the entorhinal and parahippocampal cortices (p's<0.033) without significant morphologic 43 differences. Welders also exhibited lower performance on processing/psychomotor speed, 44 executive, and visuospatial function domains (p's<0.046). Greater welding years predicted lower 45 parahippocampal FA (p=0.011), where greater short-term welding intensity (E90) predicted worse Symbol coding digit scores (p=0.019). Blood Mn and Cu levels demonstrated robust relationships 46 47 with entorhinal diffusivity (p's<0.009) and story recall performance (p=0.003), respectively, 48 throughout correlation, semi-parametric regression, and Bayesian kernel machine regression 49 analyses.

50 **Discussion**: Welding fumes and related metal exposures are associated with MTL features 51 of early Alzheimer's disease. Given the ubiquitous nature of metal exposure, future studies are 52 warranted and may have public health implications.

53

#### 54 Introduction

55 There is significant concern about health consequences of environmental exposure to toxic 56 metals found in ambient air pollution including vehicle emissions, contaminated land, and 57 occupation-related activities.<sup>1-4</sup> Essential metals can be neurotoxic in high dosages,<sup>5,6</sup> whereas nonessential metals can be neurotoxic even with low exposures.<sup>7</sup> Welding fumes contain a variety of 58 59 both essential (e.g., Cu, Fe, Mn) and non-essential (e.g., Pb) metals that can cross the blood-brain barrier, accumulate in specific brain regions, and affect cellular functions.<sup>7-9</sup> Thus, welders have 60 been an epitype human population for translational research of environmental metal exposure-61 62 related neurotoxicity.

63 Triggered by the early report of neurobehavioral disorders in Mn miners,<sup>10</sup> welding-related 64 neurotoxicity studies had focused largely on Mn accumulation in the basal ganglia and its association with parkinsonism.<sup>11,12</sup> Thus, there has been a great deal of research into Mn 65 neurotoxicity using cellular and animal models.<sup>13-23</sup> The clinical syndrome called manganism 66 67 consists initially of reduced response speed, irritability, intellectual deficits, mood changes, and 68 compulsive behaviors that progresses into more prominent, irreversible neurological dysfunction upon protracted exposure.<sup>24-28</sup> Because of some similarities to Parkinson's disease, these 69 70 syndromes have been termed Mn-induced parkinsonism, although they are distinct clinically from 71 sporadic Parkinson's disease.<sup>29-32</sup>

72 Alzheimer's disease is the most common age-related neurodegenerative disorder, comprising about 50-70% of dementia cases.<sup>33</sup> It is characterized pathologically by accumulations 73 of β-amyloid plaques and tau tangles in the brain, with the most prominent neuronal damage noted 74 in the hippocampus.<sup>34,35</sup> Although the major and early disease-related behavioral deficits entail 75 learning/memory problems,<sup>36</sup> the disease also affects executive, attentional, and language 76 77 functions<sup>37</sup> and progresses relentlessly. The clinical diagnosis of dementia is based on a substantial 78 reduction from previous performance levels in more than one cognitive domain that sufficiently interferes with independent daily living.<sup>38</sup> At the time of clinical diagnosis of Alzheimer's disease, 79 hippocampal atrophy (representing significant neuronal loss) is apparent.<sup>39</sup> The recent approval of 80 drugs like lecanemab may somewhat slow progression,<sup>40,41</sup> but they do not mitigate the widely 81 82 recognized need to identify addressable causes of dementia.

83 Preclinical animal studies have shown that metal exposure (e.g., Cu, Mn, and Fe) in brain 84 can lead to Alzheimer's disease-like A $\beta$  production and cognitive impairment.<sup>42-47</sup> Epidemiological studies also reported higher plasma metal levels (e.g., Al, Cd, Cu, Fe, Hg, Pb, 85 and Se) in Alzheimer's disease and related disorder (ADRD) populations.<sup>48-53</sup> Despite the basic 86 science and epidemiological data, linking chronic life-long metal exposure to age-related 87 88 neurodegenerative diseases in humans, individually or in subgroups, is challenging. This is due to 89 the difficulty of ascertaining exposure accurately (both distant or cumulative), the long-latency of 90 the diseases, and the fact that many early disease-related changes may be subtle and resemble 91 normal aging.

These challenges motivated research that used brain MRI to gauge Alzheimer's diseaserelated early changes. For example, T1-weighted MR imaging has been utilized to estimate cortical thinning or volume loss that may reflect neuronal death.<sup>54,55</sup> Recent studies suggested distributed brain structures (*e.g.*, fornix, cingulum, entorhinal and parahippocampal cortices, posterior cingulate, and precuneus) may exhibit changes early in the Alzheimer's disease process.<sup>56-58</sup> Among these brain regions, medial temporal lobe (MTL) memory areas that include the

98 hippocampus and entorhinal and parahippocampal cortices may play a key role in Alzheimer's 99 disease-related cognitive processes, particularly learning/memory.<sup>59,60</sup> Previous MRI studies 100 reported MTL morphometric (*e.g.*, atrophy, shape) and diffusivity (reflecting microstructural 101 integrity) changes in early-stage Alzheimer's disease or at-risk populations (*e.g.*, MCI; mild 102 cognitive impairment) who subsequently converted to Alzheimer's disease.<sup>61-63</sup> Some reported 103 entorhinal, rather than hippocampal, areas may better predict future Alzheimer's disease 104 conversion.<sup>63,64</sup>

Previously, we and others have reported hippocampal differences in metabolite ratios, 105 water molecule diffusivity, and volume<sup>65-68</sup> and learning/memory performance-decline in welders 106 or other subjects with metal exposures.<sup>69-72</sup> We sought to understand better how welding fume 107 108 exposure affects MTL structural metrics and cognition. Our overall hypothesis was that welding 109 fume exposure is associated with MTL structural and cognitive changes as seen in early 110 Alzheimer's disease. We tested three specific hypotheses: H1) Welders will have higher medial 111 (MD), axial (AD), radial (RD) diffusivity, and lower fractional anisotropy (FA) values in MTL 112 structures than controls; H2) Welders will have lower performance on processing/psychomotor 113 speed, executive, and learning/memory tasks than controls; and H3) In welders, MTL diffusion 114 features will link welding fume exposure to neurobehavioral measures. We also explored the 115 effects of mixed-metal exposures in welding fumes on MTL structural and cognitive metrics using 116 whole blood metal levels as surrogate markers.

## 117 Methods

## 118 *Study subjects*

119 Eighty subjects were recruited from central Pennsylvania (USA). Welders were defined as 120 subjects who had welded at any point in their lifetime, whereas controls had no such history. 121 Enrollment occurred between 2011-2013 and overlapped such that participants were recruited 122 equally over this timeframe. All subjects answered negatively for past Parkinson's disease 123 diagnosis or other neurological disorders and had Movement Disorder Society Unified Parkinson's 124 disease Rating Scale<sup>73</sup> motor exam sub scores (UPDRS-III) < 15. Global cognition was measured 125 by the Montreal Cognitive Assessment battery (MoCA). All subjects were male with a Mini-126 Mental Status Examination (MMSE) scores >24 or MoCA >19. Age and years of education also 127 were acquired. Forty-two welders and 31 controls completed the MRI acquisition with good 128 quality images (five welders and two controls were excluded). Written informed consent was obtained in accordance with the Declaration of Helsinki and approved by the Penn State Hershey 129 130 Internal Review Board.

#### 131

## Ascertainment of welding fume exposure and metal blood levels

We utilized established exposure questions<sup>65</sup> to estimate the following metrics: 1) recent exposure in the 90 days prior to the study visit including hours welding [HrsW<sub>90</sub> = (weeks worked) \* (h/week) \* (fraction of time worked related directly to welding) and E<sub>90</sub> (an estimate of the cumulative exposure to welding fumes)], and 2) lifetime exposure including welding years [(YrsW=years spent welding during the subjects' life) and ELT (an estimate of cumulative exposure to welding fumes over the individual's life)].<sup>65</sup>

We obtained whole blood the morning of the study (ca. 0800 h), the same day that cognitivetests and brain MRI were obtained. After digestion, the samples were analyzed for trace minerals

including Ca, Cr, Cu, Fe, K, Mg, Mn, Na, Pb, Se, Sr, and Zn using the Thermo (Bremen, Germany)
Element 2 SF-ICP-MS equipped with a concentric glass nebulizer and Peltier-cooled glass
cyclonic spray chamber. Bulk mineral concentrations were determined by ICP-OES (Optical
Emission Spectrometry) analysis on the Thermo iCAP equipped with a polypropylene cyclonic
spray chamber at the University of North Carolina, Chapel Hill, NC, USA.<sup>65</sup>

## 145 *Neuropsychological tests (NPTs) and scores*

146 Six neurobehavioral domains were examined: (1) processing/psychomotor speed; (2) 147 executive function; (3) language; (4) learning/memory; (5) visuospatial processing; and (6) 148 attention/working memory. Subtests from the Repeatable Battery for the Assessment of 149 Neuropsychological Status (RBANS)<sup>74</sup> were used to assess language, visuospatial processing, and 150 learning and memory. Processing/psychomotor speed, executive function, and attention/working 151 memory domains were evaluated using subtests from the Wechsler Adult Intelligence Scale-Third Edition (WAIS-III),<sup>75</sup> Trail Making Tests (A and B),<sup>76</sup> Stroop Test,<sup>77</sup> Delis-Kaplan Executive 152 Function System (D-KEFS),<sup>78</sup> and Wechsler Memory Scale- Third Edition (WMS-III).<sup>79</sup> Tests were 153 154 administered by an experienced examiner. Specific domains and tests follow.

155 **Processing/psychomotor speed:** During the Symbol Search subjects were 156 presented with a set of symbols and asked to report whether the provided set contained a particular symbol. In the Stroop-Word test,<sup>80</sup> color words (e.g., "RED," "GREEN," and "BLUE") were 157 presented randomly in black ink. Subjects were asked to read the words as quickly as possible. In 158 159 the *Stroop-Color* test,<sup>80</sup> each item was written as "XXXX" printed either in red, green, or blue ink. 160 Subjects were asked to name the colors as quickly as possible. During the Trail Making-A test, 161 subjects were required to connect numbers from 1 to 25 consecutively on a worksheet as quickly 162 as possible.

*Executive function:* In the *Symbol-Digit Coding* subtest, subjects performed a timed task
to match symbols to designated numbers. During the *Stroop-Color-Word* subtest, the words "RED,"
"GREEN," and "BLUE" were printed in non-corresponding colors (e.g., the word "RED" printed
in green ink). Subjects were asked to name the ink color of the printed words. In the *Trail Making- B*, subjects were required to connect numbers (from 1 to 13) and letters (from A to L) consecutively
in an alternating sequence (e.g., 1-A-2-B etc.). During the *Phonemic Fluency* subtest from *D-KEFS*,
subjects generated words beginning with a particular letter (e.g., "F") within one minute.

*Language:* In the *Picture Naming* test, subjects were asked to name 10 familiar objects.
 During the *Semantic Fluency* test, subjects generated as many words within a restricted category
 (fruits/vegetables or zoo animals) as possible within one minute.

173 Learning/memory: In the List Learning test, a non-organized list of 10 words was 174 presented orally and subjects immediately recalled the word list. Four learning trials were 175 performed where subjects were encouraged to recall the words in any order. During the Delayed 176 List Recall test, subjects recalled the same word list after ca. 20-min delay. For the Immediate 177 Story Recall test, subjects were presented with a short prose passage and immediately reproduced 178 the story they heard. In the Delayed Story Recall test, subjects recalled the story after ca. 20-min 179 delay. For the Delayed Figure Recall test, subjects reproduced a figure after a ca. 20-min delay.

*Visuospatial processing:* This was evaluated with *Line Orientation* and *Figure Copy* subtests from the *RBANS*. In the *Line Orientation test*, subjects were presented with a pair of angled

lines and asked to match them to two numbered lines on the display. During the *Figure Copy*subtest, subjects copied a complex figure.

Attention/working memory: In the Digit Span test, subjects orally were presented with a series of increasing digits, and asked to recite the digits in the presented or reversed order. In the Spatial Span test, a three-dimensional board with ten blocks was used and a series of increasing blocks were presented in a specific, predetermined pattern. Subjects were asked to reproduce the same pattern by pointing to the blocks in forward or reverse order. In the *Letter-Number Sequencing* test, subjects orally were presented with mixed sequences of digits and letters and asked to reproduce the digits in ascending order, followed by the letters in alphabetical order.

Individual raw neuropsychological test scores were converted to age-adjusted norm scores (e.g., T-scores or scaled scores). In order to unify these scores, the normative scores then were converted to z-scores [(individual norm-based scores – mean norm score) / (standard deviation of the norm score)]. Z-scores for the *Stroop (Stroop-Word, Stroop-Color, and Stroop-Color-Word), Trail Making- A* and *-B, Phonemic Fluency, Digit Span* tests were calculated based on age- and education-adjusted normed scores.<sup>76,80-83</sup> *Phonemic Fluency* subtest scores additionally were adjusted for race.<sup>82</sup>

## 198 *MRI acquisition and processing*

199 All MR images were acquired using a Siemens 3 T scanner (Magnetom Trio, Erlangen, 200 Germany) with an 8-channel head coil. First, high-resolution T1-weighted (T1W) and T2-weighted 201 (T2W) images were acquired for anatomical segmentation. For T1W images, MPRAGE sequences 202 with Repetition Time (TR)/Echo Time (TE)=1540/2.3 ms, FoV/matrix=256x256/256x256 mm, 203 slice thickness=1 mm, slice number=176 (with no gap), and voxel spacing 1x1x1 mm were used. 204 T2W images were obtained using fast-spin-echo sequences with TR/TE=2500/316 ms and the 205 same spatial resolution as the T1W images. For R1, TR/TE=15/1.45 ms, flip angles=4/25°, 206 FoV/matrix=250x250/160x160 mm, slice thickness=1 mm, slice number=192, and voxel 207 spacing=1.56x1.56x1 mm were used. R2\* images were acquired using five TEs ranging from 8-208 40 ms with an interval of 8 ms, TR=51 ms, flip angle= $15^{\circ}$ , FoV/matrix= $230 \times 230/256 \times 256$  mm, 209 slice thickness=1.6 mm, and slice number=88 were used. For DTI, TR/TE=8300/82 ms, b 210 value=1000  $s/mm^2$ , diffusion gradient directions=42 and b=0scans, 7 211 FoV/matrix=256×256/128×128 mm, slice thickness=2 mm, and slice number=65 were used.

212 **Regions of Interest:** Medial temporal brain regions that previously had reported Alzheimer 213 disease-related early changes (hippocampus, and entorhinal and parahippocampal cortices; Figure 214 1) were selected as regions-of-interest (ROIs). ROIs were defined for each subject using 215 Freesurfer.<sup>84</sup> Segmentation quality then was confirmed visually by a reviewer blinded to group 216 assignment.

217 Morphologic Metrics: Hippocampal volume segmentation and cortical parcellation for 218 calculation were performed with the Freesurfer image thickness analysis suite (http://surfer.nmr.mgh.harvard.edu/). Processing included motion correction, removal of non-219 brain tissue using a hybrid watershed/surface deformation procedure <sup>85</sup>, and automated Talairach 220 221 transformation. Deep gray matter volumetric structures including the hippocampus then were 222 segmented and cortical gay matter structures including entorhinal and parahippocampal cortices 223 were parcellated.<sup>86,87</sup>

224 Diffusion Metrics: DTI quality control and tensor reconstruction were performed using 225 DTIPrep<sup>88</sup> that first checks diffusion images for appropriate quality by calculating the inter-slice 226 and inter-image intra-class correlation, and then corrects for the distortions induced by eddy 227 currents and head motion. DTI maps then were estimated via weighted least squares. The DTI 228 maps were co-registered onto T1/T2W images using ANTS, and the transformation matrix was 229 applied inversely to bring the hippocampal region to the DTI maps. Four DTI indices [fractional 230 anisotropy (FA), AD (axial diffusivity), RD (radial diffusivity), and MD (mean diffusivity)] were calculated out of three diffusivity eigenvalues ( $\lambda 1$ ,  $\lambda 2$ ,  $\lambda 3$ ).<sup>89</sup> FA is a weighted average of pairwise 231 232 differences of the three eigenvalues and may represent the degree of diffusion anisotropy. AD is 233 the largest eigenvalue ( $\lambda$ 1) and RD is an average of the remaining two eigenvalues, both of which 234 may indicate the orientation of the diffusion. MD is an average of the three eigenvalues, providing 235 the overall diffusion magnitude <sup>89</sup>.

#### 236 Statistical analysis

237 Group comparisons of demographic data were conducted using one-way analysis of 238 variance (ANOVA). For group comparisons of exposure metrics and whole blood metal levels, 239 multivariate analysis of variance (MANOVA) was used to control intercorrelations among 240 dependent variables. Whole blood metal levels were log-transformed to attenuate the impact of 241 potential extreme values. Group comparisons of neuropsychological and neuroimaging metrics 242 were conducted using multivariate analysis of covariance (MANCOVA). Adjusted 243 neuropsychological z-scores were used for the group analyses, with adjustment for education level 244 if it was not adjusted individually. For cortical thickness and DTI measures, analyses included 245 adjustment for age and education level. When comparing hippocampal volume, total intracranial 246 volume (TIV) also was used as a covariate.

247 Multiple statistical analyses were conducted to understand the relationship between 248 exposure (welding fumes and related metals), MRI, and cognitive metrics. First, Spearman partial 249 correlation analyses were used with adjustment for potential confounders. For the associations of 250 neuropsychological/MRI metrics with exposure metrics, age and education level were used as 251 covariates. For the associations of neurobehavioral/MRI metrics with individual blood metal levels, 252 we adjusted for other blood metal levels in addition to age and education level. For the associations 253 between neurobehavioral and MRI metrics, age and education level were used as covariates. Second, semi-parametric regression analyses were conducted using generalized additive models 254 that utilized both linear and spline terms.<sup>90</sup> For these analyses, neuropsychological and MRI 255 256 metrics were treated as outcome variables, whereas exposure metrics and blood metal levels were 257 treated as predictors with adjustment for age and education level. The linear or spline relationship 258 between dose (exposure)-response (MRI/cognition) variables was determined based on loess plots. 259 For neuropsychological scores, semi-parametric regression analyses additionally were conducted 260 while treating MRI metrics as predictors with adjustments of age and education level. Third, Bayesian kernel machine regression (BKMR) analyses<sup>91</sup> were conducted that flexibly model non-261 262 linear and non-additive associations between predictors (multiple metals) and outcome variables 263 (MRI/cognition) using a Markov Chain Monte Carlo (MCMC) algorithm while treating covariates-264 MRI/cognition relationships as linear. These analyses allow testing of potential metal mixture 265 effects and interactions among blood metal variables and identifying a certain metal exposure responsible for any significant exposure effect. Lastly, causal mediation analyses<sup>92-95</sup> were 266 267 conducted to test whether neurobehavioral metrics were linked to metal exposure measurements 268 1) directly or 2) indirectly via medial temporal structural metrics, with age and education level

included as covariates (Figure 2). To test mediation effects of blood metal levels onneurobehavioral metrics, other blood metal levels additionally were used as covariates.

271 A statistical significance level of  $\alpha$ =0.05 was used. Correlation analyses of 272 neuropsychological and MRI structural metrics with metal exposure measures were corrected for multiple comparisons using the Stepdown Bonferroni method<sup>96</sup> to control the familywise error rate 273 274 (FWER) at p=0.05. We report uncorrected raw p-values but indicate significant results with FWER-275 correction. SAS 9.4 or R was used for statistical analyses. We conducted all association analyses 276 in controls and welders separately since the range of some metal exposure metrics may differ 277 substantially between controls and welders. Thus, associations of pooled data may be influenced 278 by the control/welder difference rather than the exposure effect. We report the results from welders 279 in the main text and included results from controls in the supplementary material.

#### 280 Results

## 281 **Demographics and exposure features of study participants**

Welders were older (p=0.048) and had lower education years (p<0.001) than controls. There was no significant group difference in UPDRS-III or MoCA scores (p=0.326 and p=0.797, respectively; Table 1a). Welders displayed significantly higher composite metrics of welding fume exposure (p's<0.001) and whole blood metal levels of Cu, Fe, K, Mn, Pb, Se, and Zn (p's<0.026; Table 1b).

287

## Group comparison of medial temporal MRI and neurobehavioral metrics

There were no significant group differences in morphological metrics including hippocampal volume and cortical thickness in entorhinal and parahippocampal cortices with age and education level included as covariates (p's> 0.117; Figure 3a-b). Welders displayed higher diffusivity (MD, AD, and RD) values in all ROIs (p's<0.040; Figure 4a-c). FA values were significantly lower in entorhinal and parahippocampal cortices (p's <0.033), but not in the hippocampus (p=0.501; Figure 4d).

294 Welders showed overall lower cognitive performance than controls, but this did not reach 295 statistical significance (p=0.063; Table 2). In domain-wise analyses, welders performed worse in 296 processing/psychomotor speed, executive function, and visuospatial processing than controls (p's 297 <0.046), but similarly on language (p=0.487) and attention/working memory (p=0.126) tests. 298 Welders also performed poorer on learning and memory tasks, but the difference did not reach 299 statistical significance (p=0.055). For individual subtests, welders performed worse on Stroop-300 Color and Stroop-Word processing/psychomotor speed and Symbol-Digit Coding, Phonemic 301 Fluency, and Trail Making-B executive function tasks than controls. They also had lower scores 302 on Complex Figure-Copy visuospatial processing and Delayed Story Recall learning/memory tasks 303 (p's <0.049). There were no significant group differences in the remaining individual subtests (p's 304 ≥0.131).

## 305 The relationship of MRI metrics and neuropsychological scores with exposures in welders

306 Welding history as exposure of interest

307 **Diffusion MRI metrics:** Spearman correlation analyses showed that lower 308 parahippocampal FA correlated with greater YrsW (R=-0.347, p=0.026). DTI in other ROIs did 309 not correlate with any exposure metrics (p's >0.134; Supplementary Table S1b). Subsequent semi-310 parametric regression analysis confirmed that YrsW was a significant linear predictor of lower 311 parahippocampal FA ( $\beta$ =-0.0011, t=-2.69, p=0.011; Figure 5a). Higher ELT was a significant 312 linear predictor of higher hippocampal MD and RD ( $\beta$ 's>0.0227, t's>2.08, p's <0.045).

313 Neuropsychological test scores: Spearman correlation analyses revealed that lower 314 Symbol-Digit Coding scores correlated with higher  $E_{90}$  (R=-0.371, p=0.018; Supplementary Table 315 2b), whereas lower *Picture Naming* scores were associated with lower HrsW (R=0.327, p=0.039). 316 In addition, lower Judgement of Line Orientation scores were associated with higher YrsW (R=-317 0.347, p=0.028). The remaining neuropsychological scores did not correlate with any other 318 exposure metrics (p's >0.057). Semi-parametric regression analysis (Table 3) revealed that higher 319 E<sub>90</sub> was a significant linear predictor of lower Symbol-Digit Coding scores ( $\beta$ =-0.1605, t=-2.46, 320 p=0.019; Figure 5b).

321

## Welding-related blood metal levels as exposures of interest

322 Diffusion MRI metrics: Spearman correlation analyses showed that higher values of all 323 entorhinal diffusivity metrics correlated with higher Mn (R's >0.372, p's <0.030, Supplementary 324 Table S1b). Higher entorhinal FA correlated with higher Pb and Zn (R=0.369, p=0.029 for Pb and 325 R=0.434, p=0.009 for Zn). None of the DTI metrics in other ROIs correlated with any blood metal 326 levels (p's>0.054). Subsequent semi-parametric regression analysis (Table 3b) revealed that higher 327 Mn values were significant linear predictors of higher entorhinal diffusivity ( $\beta$ 's>0.2230, t's>3.01, 328 p's <0.009). Higher Pb significantly predicted higher hippocampal diffusivity (MD, AD, RD, 329  $\beta$ 's>0.0374, t's>2.43, p's <0.035), whereas Fe level predicted lower hippocampal AD ( $\beta$ =-0.3707, 330 t=-2.51, p=0.031).

331 Neuropsychological test scores: Spearman analyses revealed that lower Stroop-Word 332 scores were associated with lower Zn (R=0.400, p=0.021, Supplementary Table S2b). Moreover, 333 lower Symbol-Digit Coding scores correlated with lower Pb but higher Cu (R=0.436, p=0.011 for 334 Pb and R=-0.430, p=0.013 for Cu). The lower Symbol-Digit Coding-blood Pb association remained 335 significant after FWER correction. Lower List Learning scores correlated with lower Fe but higher 336 Mn (R=0.387, p=0.026 for Fe and R=-0.347, p=0.048 for Mn). In addition, lower Immediate and 337 Delayed Story Recall scores correlated with higher Cu (R's <-0.366, p's<0.036). Lower Delayed 338 Figure Recall scores correlated with lower Fe (R=0.444, p=0.010) but higher Mn and Zn (R's<-339 0.386, p's<0.026). The Delayed Figure Recall-blood Mn association remained significant after 340 FWER correction. The remaining neuropsychological test scores did not correlate with any other 341 blood metal levels (p's >0.055). Semi-parametric regression analyses (Table 3b) revealed that 342 higher Cu levels were a significant linear predictor of lower Symbol-Digit Coding scores ( $\beta$ =-343 3.1322, t=-2.66, p=0.017). Lower blood Fe and higher Mn were significant predictors of lower 344 List Learning and Delayed List Recall scores (B's>6.5299, t's>2.95, p's<0.008 for Fe and B's<-345 1.0018, t's<-2.54, p's<0.025 for Mn). Higher Cu was a significant linear predictor of lower 346 Immediate and Delayed Story Recall scores (B's<-3.7790, t's<-2.29, p's<0.039; Figure 6d). Higher 347 Mn levels were a significant predictor of lower *Delayed Figure Recall* scores (B=-3.1825, t=-4.50, p<0.001). 348

349 **BKMR analyses of mixed metal effects:** Higher Mn levels were significant predictors of 350 higher entorhinal AD, MD, and RD values (p's <0.05; Figure 6a-c). Higher Fe levels were a 351 significant predictor of higher *List Learning* scores (p<0.05; Figure 6d). Higher Cu levels were a 352 significant predictor of lower *Delayed Story Recall* scores (p<0.05; Figure 6e). None of the blood

353 metal levels were significant predictors of hippocampal DTI metrics. There were also neither 354 significant metal mixture nor interaction effects among multiple blood metals on DTI and 355 neurobehavioral metrics.

356

## The relationship between MTL diffusivity and neuropsychological test scores in welders

357 Spearman correlation analyses: Higher entorhinal diffusivity correlated with lower 358 Delayed List Recall scores (R's<-0.383, p's<0.018, Supplementary Table S3b). The entorhinal 359 MD-Delayed List Recall association remained significant after FWER correction. Higher 360 parahippocampal diffusivity correlated with lower Immediate Story Recall scores (R's<-0.354, 361 p's<0.025), with the parahippocampal RD-Immediate Story Recall association remaining 362 significant after FWER correction. Lower parahippocampal FA correlated with lower Symbol 363 Search and Trail Making-A scores (R's>0.429, p's<0.006) that remained significant after FWER 364 correction. Lower parahippocampal FA also correlated with lower Spatial Span (R=0.354, 365 p=0.025). Higher hippocampal MD and RD correlated with lower Trail Making-A scores (R's<-366 0.305, p's<0.025). Other DTI metrics did not correlate with any neurobehavioral scores 367 (p's>0.054).

368 Semi-parametric regression analyses: Higher entorhinal diffusivities were significant 369 linear predictors of *Delayed List Recall* scores (B's<-3.7692, t's<-2.87, p's <0.007; Figure 7a and 370 Table 4b). Higher parahippocampal diffusivity metrics were significant linear predictors of 371 Immediate Story Recall scores (B's<-5.7229, t's<-2.64, p's <0.012; 7b). Lower parahippocampal 372 FA was a significant linear predictor of lower Symbol Search and Trail Making-A scores 373 (B=14.2616, t=-2.67, p=0.012 and B=15.7459, t=2.31, p=0.027, respectively; Figure 7c-d). Higher 374 hippocampal AD was a significant linear predictor of lower *List Learning* scores ( $\beta$ =-4.7280, t=-375 2.18, p=0.035; Figure 7e). Higher hippocampal MD and RD were significant linear predictors of 376 lower *Trail Making-A* scores ( $\beta$ =-4.4631, t=-2.10, p=0.043 and  $\beta$ =-4.9733, t=-2.16, p=0.038, 377 respectively).

## 378 Causal mediation analyses: from exposure to neurobehavioral scores via MTL MRI 379 metrics in welders

380 Welding history as exposure of interest

There were significant indirect effects of higher YrsW on lower *Symbol Search* and *Trail Making-A* scores that were mediated by lower parahippocampal FA values ( $\beta$ =-0.0252, z=-2.29, p=0.022 for *Symbol Search* and  $\beta$ =-0.0282, z=-2.27, p=0.023 for *Trail Making-A*) but no significant direct or total effects (p's>0.055). There were significant total and direct effects of higher E<sub>90</sub> values on lower *Symbol-Digit Coding* scores ( $\beta$ 's<-0.1531, z's<-2.44, p's<0.014) but no significant indirect effects (p's>0.647). There were no significant direct or indirect effects of other exposure metrics on neurobehavioral scores (p's>0.065).

388 Welding related blood metal levels as exposures of interest

There were significant indirect effects of higher blood Fe on higher *List Learning* and *Recall* scores via lower hippocampal AD ( $\beta$ 's>7.5372, z's>2.11, p's<0.035), and significant total effects ( $\beta$ 's>4.4794, z's>2.16, p's<0.031) without direct effects (p's>0.726). There, however, were no significant indirect effects of other metal levels on neurobehavioral scores via MTL DTI metrics (p's>0.109). Blood Cu, Mn, and Pb levels had significant total and direct effects without significant indirect effects: For Cu, these effects resulted in lower *Symbol-Digit Coding* and

395 *Delayed Story Recall* scores (β's<-3.1633, z's<-1.97, p's<0.049). For Mn, the effects were on 396 lower *List Learning, Delayed List,* and *Figure Recall* scores (β's<-1.4742, z's<-2.01, p's<0.045).

397 For Pb, the effects led to higher *Symbol-Digit Coding* scores (β's>0.4989, z's>1.97, p's<0.048).

#### 398 **Discussion**

399 This is the first in-depth examination that used multimodal structural MRI to study multiple 400 MTL regions in welders. Consistent with our hypothesis H1, we observed a reliable pattern across 401 MTL areas of DTI features (higher AD, RD, MD, lower FA) that is consistent with findings in 402 ADRD populations. The persistent MTL DTI features in the absence of morphometric differences 403 (markers of significant macroscopic neuronal loss) suggest that these DTI metrics may serve as 404 sensitive markers for gauging early disease processes probably representing microstructural 405 integrity. Consistent with our hypothesis H2, we replicated prior findings that welders have lower 406 performance in processing/psychomotor speed and executive function domains that are associated 407 with welding history. In addition, we conducted a comprehensive analysis to understand the 408 relationship of the MTL MRI metrics with welding-related metal exposure and neuropsychiatric 409 changes and whether MTL MRI metrics may mediate metal-exposure to cognitive outcomes. We 410 noted that greater welding years (YrsW) predicted lower parahippocampal FA, whereas greater 411 short-term welding intensity (E90) predicted worse Symbol coding digit scores. MTL DTI metrics 412 (microstructural changes) mediate, at least partially, the effects of welding fumes on cognitive 413 performance, consistent with our hypothesis H3. Together, the results of the current study are 414 consistent with our key scientific premise that welding fume exposures are associated with MTL 415 microstructural features resembling early ADRD.

416 The explorative analyses on associations of seven blood metal levels (higher in welders 417 than in controls) with MRI metrics or neuropsychologic scores yielded mixed and inconsistent 418 results. This may be, in part, due to low sample size with multiple metals of interest and that blood 419 metals only represent recent, ongoing, and short-term (~3 m) exposure. In addition, different 420 metals may have different exposure-effect curves (which potentially may be non-monotonic), 421 depending on the dose level and the brain regions and cognitive metrics of interest. Nonetheless, 422 higher blood Mn and Cu levels demonstrated the most robust relationships with higher entorhinal 423 diffusivity values and lower Delayed Story Recall performance, respectively, analyzed using multiple statistical approaches including correlations, semi-parametric regression, and Bayesian 424 425 kernel machine regression. Given the ubiquitous nature of low-level metal exposure and their 426 broader public health impact, future studies are warranted.

# Welders' medial temporal microstructural features are consistent with ADRD-at risk populations

429 The hippocampus and entorhinal/parahippocampal cortices are key structures for medial 430 temporal memory tasks. The parahippocampal cortex receives inputs from widespread associative cortical areas including frontal, temporal, parietal, occipital, and cingulate cortices.<sup>97,98</sup> It then 431 432 passes information to the entorhinal cortex that, in turn, has reciprocal connections with the 433 hippocampus. Thus, the entorhinal cortex serves as a major information relay station to and from 434 the hippocampus, although the hippocampus also is connected with white matter (e.g., fornix) and diencephalic structures serving particularly long-term memory formation.<sup>60</sup> The entorhinal outputs 435 436 then are projected back to various cortical regions through the parahippocampal cortex.<sup>99,100</sup>

437 As noted in the Introduction, there have been substantial efforts towards finding reliable 438 and early markers to predict future AD conversion. Consistent with its cardinal role in memory, MTL areas appear to be one of the first regions affected by AD-related pathological changes.<sup>56,101-</sup> 439 440 <sup>103</sup> Decreased hippocampal and entorhinal volume and/or thickness have been reported as predictors for AD conversion.<sup>104,105</sup> Recent studies suggested other imaging metrics such as shape, 441 442 texture, functional networks, or water molecule diffusion in neuronal tissues may be even more 443 sensitive in capturing early AD-related alterations.<sup>63,106-110</sup> Our finding of welding fume exposure 444 relating to altered DTI metrics in all MTL areas included in the current study is consistent with the 445 concept that early ADRD-related changes are occurring without apparent volume reduction or 446 cortical thinning in these areas.

The exact neuropathological substrates underlying DTI metrics are unclear. It is speculated, however, that they reflect microstructural disorganization (*e.g.*, cytoarchitectural degeneration or demyelination processes).<sup>111</sup> Future studies with state-of-the-art MRI methods such as multi-shell diffusion imaging that utilizes multiple b-values to minimize motion or other artifacts and accurately model more detailed cellular features<sup>112,113</sup> may help dissect these neural mechanisms.

452

#### 52 Neuropsychological features in welders may be consistent with ADRD-at-risk populations

453 Our study is consistent with prior findings that welders performed worse on several neuropsychological tests.<sup>114-116</sup> We note that our welders had lower performance on the *Delayed* 454 Story Recall subtest but not learning/memory tests or List Learning/Recall and Figure Recall 455 subtests that typically estimate episodic memory in laboratory settings.<sup>117</sup> Episodic memory 456 457 involves consciously retrieving information (e.g. events) that was acquired in a particular time and 458 space.<sup>118</sup> ADRD-related neurobehavioral deficits comprise various cognitive functions including executive, attentional, and language functions. In particular, difficulties with learning/memory 459 tasks have a robust relationship to early ADRD.<sup>117,119</sup> Our finding of lower *Delayed Story Recall* 460 461 performance in our "asymptomatic" welders suggests ADRD-related early episodic memory 462 decline may occur in a task-specific way. Therefore, the earliest decline may be detected more 463 sensitively with a Story Recall task rather than other types of episodic memory tasks (e.g., word 464 list or visuospatial figure recall).

465 Our robust associations of higher entorhinal and parahippocampal diffusivity values with lower (worse) learning/memory performance is consistent with previous findings reporting MTL 466 involvement in episodic memory.<sup>120</sup> Although episodic memory is considered a crucial function 467 of the hippocampus,<sup>121</sup> the current association is not surprising since the parahippocampal and 468 entorhinal cortices provide major inputs to the hippocampus.<sup>60</sup> Consistent with our finding, 469 470 previous studies reported that lower entorhinal cortex volume, but not hippocampal volume, was associated with lower Delayed List and Story Recall scores in Alzheimer's patients.<sup>60,120</sup> In 471 472 addition, MTL DTI metrics have been associated with memory scores in both healthy elderly and Alzheimer's patients.<sup>122,123</sup> In these previous studies, DTI metrics were examined either in the 473 474 hippocampus alone or in conjunction with MTL white matter. This study extended previous work 475 to entorhinal and parahippocampal areas and demonstrated, for the first time to our knowledge, a 476 robust association of entorhinal and parahippocampal diffusivity with episodic memory 477 performance among welders.

Interestingly, MTL regions seem to be involved not only in memory but also in
 processing/psychomotor speed performance. The underlying mechanism is not clear, but the
 results are consistent with previous reports of significant associations between parahippocampal

481 gyrus thickness and processing speed scores, particularly when performing visuospatial tasks.<sup>124,125</sup> Speedy information processing may be crucial for various functional abilities including 482 483 attention, encoding and retrieval of to-be-remembered information, reasoning, decision making, 484 and visuospatial perceptions.<sup>126</sup> Recent structural and functional neuroimaging studies also suggested that the hippocampus may be involved in various neuropsychological tasks such as 485 working memory, executive function, spatial processing, and sensorimotor integration.<sup>111,127-130</sup> 486 487 Given previous findings reporting associations between slowed psychomotor speed and risk for dementia development,<sup>131-133</sup> the present results may provide potential neural correlates 488 489 responsible for ADRD-related slowed psychomotor speed. Collectively, our findings are 490 consistent with the concept that our welders display cognitive deficits/patterns reported in ADRDat-risk populations and support ADRD-related early changes in welders.<sup>107,117</sup> 491

492

## Understanding the path from metal exposure to MTL MRI and cognitive performance

We employed multiple analytical steps and statistical methods to understand the complex relationship between welding fume-related metal exposure and MTL MRI and cognitive findings. First, we found that long-term exposure metrics (e.g., ELT and YrsW) were significant predictors of hippocampal and parahippocampal DTI metrics, validating that MTL microstructural features are indeed related to long-term welding exposure. In addition, mediation analyses suggested that YrsW indirectly impaired processing/psychomotor speed tasks (lower *Symbol Search* and *Trail Making-A* scores) via lower parahippocampal FA values.

500 Second, we also noted a short-term exposure metric that takes exposure intensity into 501 account (E90) predicted lower Symbol-Digit Coding scores, a task where subjects matched symbols 502 to designated numbers under time pressure. This task can be demanding for adults, particularly 503 elderly adults, because it requires executive function skills to some degree in addition to 504 appropriate psychomotor speed. Our result suggests that even short-term metal exposure with 505 higher intensity may interfere with proper performance on executive function tasks. The finding 506 motivated the exploration of metal levels in blood, usually, depending on the metal, a surrogate 507 marker for short-term metal exposure. We considered seven metals in our exploration because they 508 are higher in welders, acknowledging that our statistical power was limited if we rely on 509 significance after FWER-correction of multiple comparisons. Thus, we employed multiple 510 approaches, and use the level of consistency in results to inform our conclusions.

511 Blood Mn and Cu levels demonstrated robust relationships with entorhinal diffusivity and 512 Delayed Story Recall performance, respectively. The association persisted throughout semi-513 parametric regression, and BKMR analyses. The finding of blood Mn-entorhinal diffusivity 514 association is not surprising, given that Mn has been the metal of focus on welding-related toxicity, 515 as we reviewed in Introduction. Lower FA values in white matter regions (e.g., corpus callosum and frontal white matter areas) have been reported in both welders and controls.<sup>134</sup> It is however, 516 517 unclear whether the blood Mn represents the long-term occupational exposure or short-term 518 intensity. However, the finding of the association between blood Cu and cognitive performance 519 among welders is novel. Chronic Cu exposure has been associated with increased brain Cu accumulation in the basal ganglia and hippocampus<sup>46</sup> and increased risk for Alzheimer's 520 521 disease.<sup>135</sup> Cu in brain has a high affinity for  $\beta$ -amyloid plaques that may enhance inflammatory responses, reactive oxygen species (ROS) generation, and fibril formation leading to increased β-522 amyloid aggregates that is a characteristic feature of ADRD.<sup>136</sup> Future studies of welding fume 523 524 exposure need to include Cu as an important factor worthy of consideration.

525 Our analyses also yield two serendipitous observations which were unexpected but 526 intriguing. First, higher blood Fe levels in welders predicted a better List Learning/Recall score. 527 Subsequent mediation analyses suggested that higher blood Fe is linked to higher List 528 Learning/Recall scores via lower hippocampal AD values. These results imply that higher 529 peripheral Fe may be a protective factor against microstructural changes and subsequent 530 performance deficits. This finding appears contradictory to previously reported neurotoxic effects 531 of Fe exposure,<sup>9,137</sup> yet consistent with reports of complexed relationship between peripheral Fe levels and cognitive functions.<sup>138-140</sup> It is also worth noting that higher brain Fe accumulation, 532 which has a very different pathophysiological context than blood Fe, was reported in subjects with 533 534 AD pathology or cognitive impairments <sup>141,142</sup> but this is not well established in asymptomatic populations.<sup>143,144</sup> Second, we observed that blood Pb levels predicted higher hippocampal 535 536 diffusivity (AD, RD, MD) and Entorhinal AD (p < 0.036) in semi-parametric regression analyses, 537 yet directly linked to higher symbol-digit coding scores in causal medication analyses. The results 538 of the two analyses may appear contradictory at first, but reasonable given the unique distribution 539 and kinetics of Pb in the human body, as distinct from short-term levels of metals such as Fe in the 540 blood. Greater than 90% of Pb deposits in bone with a half-life on the order of decades.<sup>145,146</sup> In addition, Pb deposited in bone is itself a source of endogenous exposure as it gradually is mobilized 541 542 into circulation, exposing critical organs to Pb even with no recent exposure.<sup>147</sup> Thus, blood Pb 543 levels may represent both long-term and short term exposure. Based on this, we speculated that as 544 a long-term exposure metric, Pb may negative impact MLT structures, yet as a short-term exposure 545 metric, Pb may competing with transport of other toxic metals (such as Cu) into the brain and 546 preventing its negative impact on cognitive performance of our welders. Together, these findings 547 suggest the importance that future studies need to consider the dynamics and reversibility of 548 mixtures of welding-related metals, as well as separately analyzing each brain region and metric 549 of cognitive outcomes, in both welders and controls.

## 550 *Limitations and conclusions*

This study has several limitations. First, the sample sizes were relatively small, and future 551 552 validation research should, where possible, utilize larger cohorts. Second, we measured several 553 blood metal levels, but it might be possible that the effects observed were due to an unmeasured 554 metal or a co-occurring environmental factor. Additional studies assessing alternative metals may 555 provide further insight into the actions of metal co-exposures, something of both scientific and 556 public health relevance. Lastly, it is notable that our welder cohort, though many participants had 557 long histories of welding work, had relatively lower welding fume exposure levels compared to many other prior studies (i.e., 11.0 vs. >14.2 µg/L for mean blood Mn; 22.7 vs. >30-50 µg/L for 558 mean blood Pb).<sup>67,71,148-150</sup> This suggests that other groups with relatively low but chronic exposure 559 560 to the same metals in the welding-fume profile may suffer similar sequalae as a result of 561 environmental exposure.

## 562 Funding

563 This work was supported by NIH grants R01 ES019672, R01 NS060722, U01s NS082151 564 and NS112008, the Hershey Medical Center General Clinical Research Center (National Center 565 for Research Resources, UL1 TR002014), the Penn State College of Medicine Translational Brain 566 Research Center, the PA Department of Health Tobacco CURE Funds, the National Research 567 Foundation of Korea (2019R1G1A109957511; RS-2023-00247689), and Dong-A University 568 Research Fund.

#### 1122 Table 2. Neuropsychological test results for controls and welders

1123 Data represent the mean  $\pm$  SD. Test scores were converted to z-scores based on age- (denoted as <sup>a</sup>) 1124 or age- and education- (denoted as <sup>b</sup>) adjusted norm (t- or scaled) scores. Higher scores indicate 1125 better performance. Multivariate analysis of covariance (MANCOVA) was conducted with Group 1126 as the independent variable and individual subtests of each cognitive domain as the dependent 1127 variables. Bold numbers indicate significant result at p<0.05. Education level was additionally 1128 adjusted for the cognitive domains language, visuospatial processing, learning/memory, and

1129 *attention/working memory.*

Table 4. Semi-parametric regression analyses to determine medial temporal structural MR
predicting neurobehavioral metrics for controls (a) and welders (b)

Data represent parameter estimates and corresponding *T*- and *p*-values of *MTL MRI* metrics to predict neurobehavioral metrics.

## **Figures and legends**

Figure 1. Automatically segmented regions of interest [hippocampus, entorhinal and parahippocampal cortices] on T1-weighted MPRAGE images.

Figure 2. Mediation models to test effects of exposure (composite metrics of welding exposure; blood metal levels) on neurobehavioral metrics while medial temporal DTI metrics serve as mediators after controlling for potential confounders (age; education level; blood levels of other metals): 1) A indicates direct effects of exposure on neurobehavioral metrics that are not mediated by medial temporal DTI metrics; 2) B\*C indicates mediation effects of exposure on neurobehavioral metrics.

Figure 3. Morphologic MRI measures in welders and controls: a) hippocampal volume; b) cortical thickness in entorhinal and parahippocampal cortices.

Figure 4. Diffusion tensor imaging (DTI) a) mean (MD); b) axial (AD), c) radial (RD) diffusivity, and d) fractional anisotropy (FA) of medial temporal structures for welders and controls.

Figure 5. Scatter plots show a) adjusted parahippocampal FA values (y-axis) vs. YrsW (x-axis) in welders; b) adjusted *Symbol-Digit Coding* scores (y-axis) vs. E<sub>90</sub> (x-axis). Adjusted values indicate values after controlling for age and education level.

Figure 6. BKMR (Bayesian kernel machine regression) univariate dose-response associations of metal mixture components with medial temporal DTI and neurobehavioral scores with 95% confidence interval band; a) estimate of entorhinal MD values (y-axis) vs. log-transformed blood Mn (x-axis) in welders; b) estimate of entorhinal AD values (y-axis) vs. log-transformed blood Mn (x-axis) in welders; c) estimate of entorhinal RD values (y-axis) vs. log-transformed blood Mn (x-axis) in welders; d) estimate of *List Learning* scores (y-axis) vs. log-transformed blood Fe (x-axis) in welders; e) estimate of *Delayed Story Recall* scores (y-axis) vs. log-transformed blood Cu (x-axis) in welders. Age and education level were used as covariates. Other blood metal levels than the metal of interest in the analysis were fixed at the median on the y-axis.

Figure 7. Scatter plots show a) adjusted *Delayed List Recall* scores (y-axis) vs. adjusted entorhinal MD values (x-axis); b) adjusted *Immediate Story Recall* scores (y-axis) vs. adjusted parahippocampal RD values (x-axis); c) *Symbol Search* scores (y-axis) vs. adjusted parahippocampal FA values (x-axis); d) adjusted *Trail Making-A* scores (y-axis) vs. adjusted parahippocampal FA values (x-axis); e) adjusted *List Learning* scores (y-axis) vs. adjusted hippocampal AD values (x-axis) in both welders and controls.
