### **Risk-adjusted rates on post-discharge 30-day mortality**

The monthly rates in this study included unadjusted and risk-adjusted rates calculated for each calendar month across all patients with a given condition. For risk-adjustment we created a logistic regression model (readmission/mortality) with the outcome as the response variable and the CMS covariates as the independent variables for each of the 4 strategies of covariate identification. This ensured that the models were built for each strategy separately – replicating what others would be able to do with the data. The monthly risk-adjusted mortality rates were calculated independently for each strategy by assessing the covariate distribution in these months relative to the covariate distribution and observed rates across the entire study. The period-wise average rates and the variance of these rates were calculated as an average of monthly rates within a given period weighted by the number of patients included in the study for each month. The rates were no different from the period-wise rates derived from all patients across a period directly.

### **Period-wise change models**

We created dummy coded data to evaluate for change in rates between the baseline and pre-HRRP periods, and between pre-HRRP and HRRP anticipation periods, and HRRP anticipation and penalty periods. In these analyses, the two consecutive periods compared were modelled as two temporal states, i.e. the first of two were assigned as state 0 and the latter period was assigned a state 1. The excess change in mortality relative to HRRP announcement was calculated as marginal effects in regression

models, comparing differences in average changes between the baseline and pre-HRRP periods as the control, and between pre-HRRP and HRRP anticipation as the experimental condition. Similarly, excess change in mortality after HRRP penalties was calculated as the differences in average changes between models that included baseline and pre-HRRP periods as the control, and between HRRP anticipation and HRRP penalty periods as the experimental condition

**Theoretical arguments against ignoring temporal mortality trends within period**

We assessed the theoretical framework underlying the assessment of trends related to an intervention as changes in average rates across periods. We assumed that there were 6 months in a hypothetical assessment, categorized into 3 periods p, q and r, each comprised of 2 months. Period ‘r’ would represent the period after an intervention.

In the first case, which is a negative control, we assumed that the outcome changed across the 6 months linearly at a rate of  $Y = a + b \cdot \text{month}$ , where ‘a’ is the rate of outcome before the period of observation and ‘b’ is the slope of change in the rate of the outcome. In this example, the difference in averages across consecutive 2-month periods was ‘2b’, with no excess increase in rate of outcome in ‘r’.

Case 1: Outcome changed at a constant rate $Y = a + b \cdot \text{month}$					
Month	E(y)	Period name	Mean for period	Difference between consecutive periods	Excess difference (ascribed to period r)
0	a	p	$(2a+b)/2$	q - p = 2b	$(r-q) - (q-p) = 0$
1	a+b				
2	a+2b	q	$(2a+5b)/2$	r - q = 2b	
3	a+3b				
4	a+4b	r	$(2a+9b)/2$		

5	a+5b				
---	------	--	--	--	--

In the second case, which is also a negative control, we assumed that the outcome changed across the months 0 to 2 linearly at a rate of  $Y = a + b \cdot \text{month}$ , but the slope increased by a constant 'c' from months 3 to 5, such that Y in months 3, 4 and 5 was  $Y = a + (b+c) \cdot \text{month}$ . By design, there was no change in slope at month 4, relative to month 3, and therefore, there was no increase in the rate of the outcome that should be ascribed to the third period ('r'). However, the model assessing changes in average rates across periods would ascribe an inflection in the rate of outcome to this period.

Case 2: Intervention implemented in month 4, month 3 starts observing increase in outcome rate by c, $Y = a + (b + c) \cdot \text{month}$					
Month	E(y)	Period name	Mean for period	Difference between consecutive periods	Excess difference (ascribed to period r)
0	a	p	$(2a+b)/2$	$q - p = 2b + 3c/2$	$(r-q) - (q-p) = 3c/2$
1	a+b				
2	a+2b	q	$(2a + 5b + 3c)/2$	$r - q = 2b+3c$	
3	a+3(b+c)				
4	a+4(b+c)	r	$(2a + 9b + 9c)/2$		
5	a+5(b+c)				

In the third case, which was a positive control, we assumed that the outcome changed across the months 0 to 3 linearly at a rate of  $Y = a + b \cdot \text{month}$ , but the slope increased by a constant 'c' from months 4 to 5, such that Y in months 4 and 5 was  $Y = a + (b+c) \cdot \text{month}$ . By design, we modeled the effect of the intervention in the outcome that occurred in the 3<sup>rd</sup> period 'r'. The model accurately ascribed an inflection in the rate of outcome to this period.

Case 3: Intervention implemented in month 4, month 4 also starts observing increase in outcome rate by c, $Y = a+(b + c)*\text{month}$					
Month	E(y)	Period name	Mean for period	Difference between consecutive periods	Excess difference (ascribed to period r)
0	a	p	$(2a+b)/2$	q - p = 2b	$(r-q) - (q-p) = 9c/2$
1	a+b				
2	a+2b	q	$(2a+5b)/2$	r - q = 2b+9c/2	
3	a+3b				
4	a+4(b+c)	r	$(2a+9b+9c)/2$		
5	a+5(b+c)				

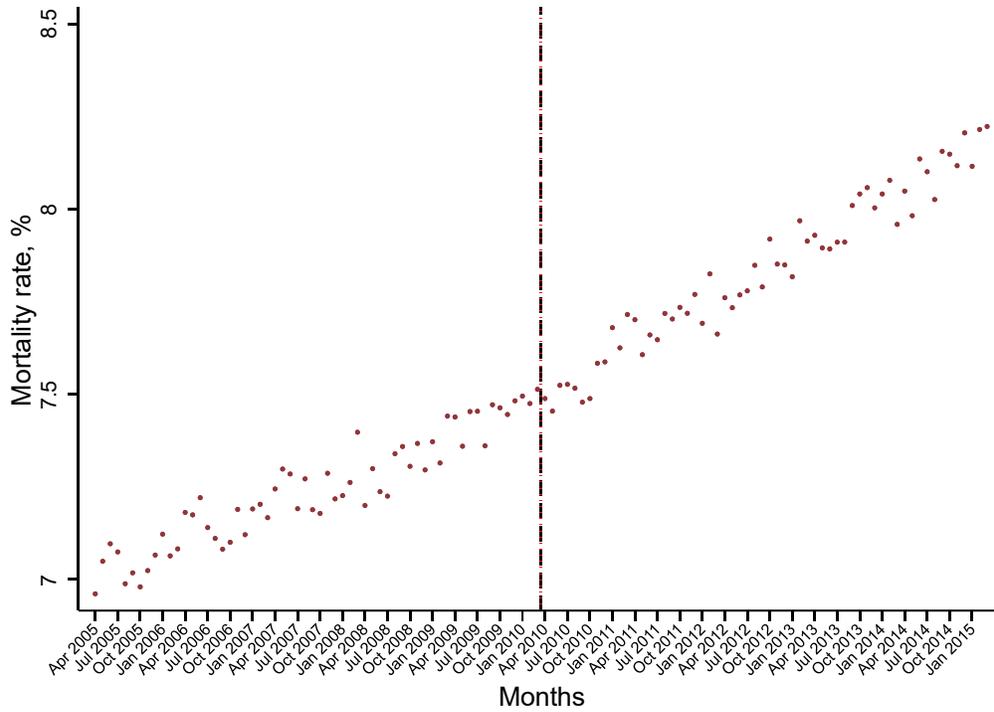

### Interrupted time series models

For mortality calculated as monthly rates, we modelled the effect of HRRP announcement and penalties as changes in slope of monthly rates using an interrupted time series framework. These models were identical to those deployed in our previous paper. We parameterized month as a count from 1 to 120, assumed the adjusted estimates were linearly associated within a month, and assumed that after accounting for month, no serial correlation existed. We weighted each monthly risk-adjusted estimate by the inverse of its variance. We parameterized the effect of policies to have a gradual relationship with the mortality rates, thereby only affecting the slope of the mortality regression curve. In this analysis, we constructed a linear spline across monthly risk-adjusted rates of each outcome with knots at calendar months separating the baseline and pre-HRRP period, and at HRRP's announcement (April 2010), and the implementation of its financial penalties (October 2012) – the knots were symmetric placed at 30-month intervals. We assessed the slopes of the spline both before and

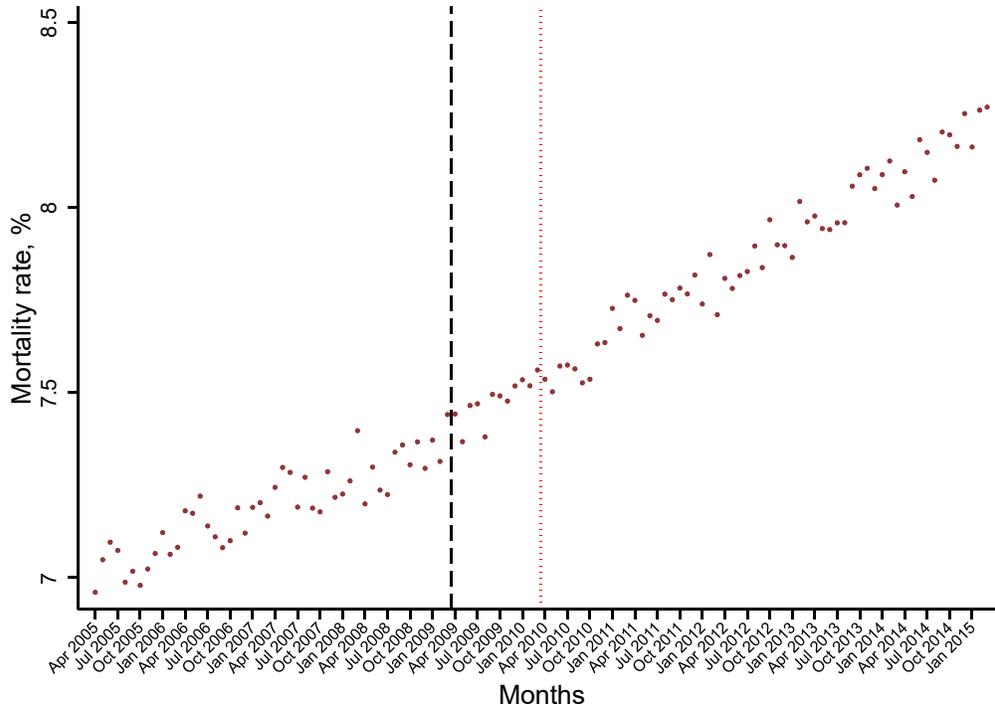

after each transition, and for changes in the slope of the time trends in these outcomes at these predefined knots.

Risk-adjustment strategy	Period	Slope during the period	Change in slope at period transition	P-value for slope change
Simulated change at HRRP announcement	Baseline	0.007 (0.006, 0.009)		
	Pre-HRRP	0.009 (0.007, 0.01)	0.001 (-0.001, 0.004)	0.37
	HRRP anticipation	0.011 (0.010, 0.013)	0.003 (0.001, 0.005)	0.02
	HRRP penalty	0.012 (0.011, 0.014)	0.001 (-0.002, 0.003)	0.59
Simulated change 12 months before HRRP announcement	Baseline	0.007 (0.005, 0.009)		
	Pre-HRRP	0.01 (0.009, 0.011)	0.003 (0.001, 0.006)	0.02
	HRRP anticipation	0.012 (0.011, 0.013)	0.002 (-0.001, 0.004)	0.17
	HRRP penalty	0.012 (0.01, 0.014)	0.000 (-0.002, 0.003)	0.88
Simulated change 24 months before HRRP announcement	Baseline	0.007 (0.005, 0.009)		
	Pre-HRRP	0.012 (0.011, 0.013)	0.005 (0.002, 0.008)	<0.001
	HRRP anticipation	0.012 (0.01, 0.013)	0.000 (-0.003, 0.002)	0.71
	HRRP penalty	0.012 (0.011, 0.014)	0.001 (-0.002, 0.003)	0.66

The 95% confidence intervals have not been adjusted for multiple testing. Abbreviation: HRRP – Hospital Readmissions Reduction Program
