## A. Poisson regression

A Poisson regression model applies a generalized linear model with a logarithmic link function under the assumption that the response variable is Poisson distributed and that the logarithm of the expected value $\mu$ can be expressed in a linear combination of $k$ parameters (1) ${ }^{1}$

$$
\begin{equation*}
\log \mu=\beta_{1} * x_{1}+\beta_{2} * x_{2}+\cdots+\beta_{k} * x_{k} \tag{1}
\end{equation*}
$$

When counts are measured for a unit that varies across individuals an offset can be included in the model, allowing for a rate interpretation (3). UK Biobank participants were recruited over a period of four years and for each participant hospital admissions were counted from recruitment to study censoring with the latter given by either death or 31 March 2015, the censoring date for the linked Hospital Episode Statistic data. We ignore emigration, which is estimated to occur at low rates (0.3\%) in this cohort (1).To correct for the varying times on study, the logarithm of observed person-years $t$ is added to the linear equation as an offset (2).

$$
\begin{equation*}
\log \mu=\log t+\beta_{1} * x_{1}+\beta_{2} * x_{2}+\cdots+\beta_{k} * x_{k} \tag{2}
\end{equation*}
$$

The modeled outcome can now be interpreted as a rate rather than a count, as becomes apparent when restructuring the equation (3).

$$
\begin{equation*}
\log \frac{\mu}{t}=\beta_{1} * x_{1}+\beta_{2} * x_{2}+\cdots+\beta_{k} * x_{k} \tag{3}
\end{equation*}
$$

Let $x_{1}$ and $\beta_{1}$ represent the exposure BMI and the corresponding parameter estimated from the Poisson regression. Then with $t$ in years and BMI in $\mathrm{kg} / \mathrm{m}^{2}$ the exponent of the coefficient $\exp \left(\beta_{1}\right)$ is the factor by which the mean value of the outcome is multiplied for a $1 \mathrm{~kg} / \mathrm{m}^{2}$ increase in BMI. More generally, given that the remaining variables are held constant, the yearly hospital admission rate increases with a factor $\exp \left(\beta_{1}\right)^{n}$ for every $n$ unit increase in BMI.

Within the context of one- and two-sample MR analyses we propose a model where the second stage linear regression of the outcome $Y_{\text {adm }}$ on the gene is replaced by a Poisson regression with the person years on study $t$ as offset. Let $\beta_{\text {exp }}$ be the exposure coefficient obtained from a linear regression of the exposure $Y_{\text {exp }}$ on the genetic instrument or risk score $G(4)$, and $\beta_{\text {out }}$ the outcome coefficient on the logarithmic scale obtained from a Poisson regression of the outcome $Y_{\text {out }}$ on the genetic instrument $G$ (5).

$$
\begin{align*}
& Y_{\text {exp }} \sim \beta_{\text {exp }} * G  \tag{4}\\
& \log \left(Y_{\text {out }}\right) \sim \log (t)+\beta_{\text {out }} * G \tag{5}
\end{align*}
$$

As the Poisson model is linear on the log scale, the two coefficients are compatible and a valid ratio can be obtained, with the final IV estimate $\beta_{\mathrm{IV}}$ of the rate coefficient given by the exponent of this ratio (6).

$$
\begin{equation*}
\beta_{I V}=\exp \left(\frac{\beta_{o u t}}{\beta_{\mathrm{exp}}}\right) \tag{6}
\end{equation*}
$$

In the one-sample MR framework, as in the traditional linear model, using the Wald ratio approach as detailed here is equivalent to performing a two-stage regression, where the fitted values of the exposure-gene regression (4) would be included as a covariate in a Poisson regression with time on study as offset. We elected to use the Wald ratio approach, which allows for a comparatively straightforward correction of IV estimate standard error using Taylor series expansions², applied on the logarithmic scale.

## B. Two-sample summary MR approaches

Four two-sample MR approaches were used to investigate the effect of BMI, WHR and WHRadjBMI on yearly hospital admission rate: 1) the random effects exact weights inverse-variance weighted (IVW) estimator ${ }^{3}$; 2) the random effects MR-Egger estimator ${ }^{4}$; 3) the penalized median estimator ${ }^{5}$; 4) the weighted mode estimator ${ }^{6}$. Below, some detail is provided on these methods.

For the random effects models, Wald ratios are estimated for each SNP separately and combined using a random effects meta-analysis approach. The traditional IVW estimator uses weights derived from the inverse variance of the SNP-outcome coefficient. The exact weights IVW estimator derives weights in a slightly different way, using a limited information maximum-likelihood (LIML) approach in which the weight term is allowed to be a function of the causal-effect parameter. This approach ensures the estimator is naturally robust against regression-dilution bias. ${ }^{3}$

The random effects MR-Egger model is pleiotropy-robust and, unlike the IVW estimator, does not constrain the intercept to zero. The MR-Egger regression intercept can be interpreted as the average pleiotropic effect of all variants. Verifying whether the observed intercept is statistically different from zero serves as a test for horizontal pleiotropy. ${ }^{4}$

Heterogeneity was investigated using the IVW-based Cochran's-Q and the MR-Egger based Rucker's Q. As a rule of thumb, when $Q$ is much larger than $L-1$, with $L$ the number of SNPs used in the analysis, heterogeneity is detected. Assuming the observed heterogeneity is a result of horizontal pleiotropy, we can account for this by implementing a random effects IVW model or a random effects MR-Egger model in favour of either fixed effects model. ${ }^{7}$ Plots of these two $Q$ statistics as calculated for each SNP in a
leave-one-out analysis, were used for the visual identification of outliers, which were removed in a sensitivity analysis with the purpose of verifying estimator consistency.

The median estimate is given by the median ratio estimate of ordered ratios. The simple median estimator will give a consistent estimate of the causal effect when at least $50 \%$ of the considered variants are valid, whereas the penalized weighted median estimator will do so when at least $50 \%$ of the weights come from valid instruments. In the penalized weighted median estimator, Cochran's Q statistic is used to quantify heterogeneity and more heterogeneous, outlying variants are down-weighted. ${ }^{5}$

The mode estimate is given by the mode of the Wald ratio estimates and will consistently estimate the causal effect even if more than half of the SNPs are invalid, provided the largest homogeneous cluster is valid. Both the weighted median and mode estimators use weights derived from the inverse variance of the ratios of the gene-outcome and gene-exposure association estimates and are, under different assumptions, robust to outliers and invalid instruments. ${ }^{6}$

Table S7. Two-sample MR analysis: MR-Egger (random effects), IVW (random effects, exact weights), weighted median and weighted mode analyses of BMI ( 64 SNPs), WHR ( 34 SNPs) and WHRadjBMI ( 45 SNPs) on hospital admission rate per year in UK Biobank participants of White British ancestry. SNPs with an LD R $2<0.001$ have been retained. Rates are given per exposure unit and exposure $\operatorname{SD}$ (SDвмі $=4.6$, SDwнг=0.07) and $95 \%$ confidence intervals $(95 \% \mathrm{CI})$ are provided.

$\mathrm{BMI}=$ body mass index, $\mathrm{EA}=$ effect allele, EAF = effect allele frequency, $\mathrm{LD}=$ linkage disequilibrium, $\mathrm{MR}=$ Mendelian randomization, $\mathrm{OA}=$ other allele, $\mathrm{SE}=$ standard error, $\mathrm{WHRadjBMI}=$ waist-hip-ratio adjusted for BMI
a) These 3 SNPs exceeded the LD threshold $\left(\mathrm{R}_{2}<0.001\right)$ and were excluded from the two-sample summary MR analysis
b) The effect allele (EA) is the WHR increasing allele
c) Coefficients are given per WHR SD (0.07)
d) Coefficients are given on the logarithmic scale, obtained from a quasi-Poisson regression of hospital admission count on the relevant SNP, using person-years on study as an offset and adjusting for age, sex and the first 40 PCAs

Table S13. BMI-SNP, WHR-SNP and hospital admission count-SNP associations as used for the multivariable two-sample MR analysis of the effect of BMI and WHR on yearly hospital admission rate. Given are the 70 SNPs remaining after LD correction ( $\mathrm{R}_{2}<0.001$ ) to the joint set of BMI and WHR SNPs.

$\mathrm{BMI}=$ body mass index, $\mathrm{EA}=$ effect allele, $\mathrm{EAF}=$ effect allele frequency, $\mathrm{LD}=$ linkage disequilibrium, $\mathrm{MR}=$ Mendelian randomization, $\mathrm{OA}=$ other allele, $\mathrm{SE}=$ standard error, $\mathrm{WHR}=$ waist-hip-ratio
a) Coefficients are given per SD unit, $4.6 \mathrm{~kg} / \mathrm{m}_{2}$ and 0.07 , for BMI and WHR, respectively, consistent with the Locke (2016) and Shungin (2015) GWAS meta-analyses. For the analyses the coefficients were used on the SD scale for both exposures and rescaled to whole units for BMI and 0.1 units for WHR.
b) Coefficients are given on the logarithmic scale, obtained from a quasi-Poisson regression of hospital admission count on the relevant SNP, using person-years on study as an offset and adjusting for age, sex and the first 40 PCAs

## BMI

A

Rucker's Q

B

Figure S1. Plots for two-sample MR analysis of BMI effect (per SD, with SDвмı=4.6) on yearly hospital admission count in UK Biobank participants of White British ancestry. Effects are shown on the $\log (r a t e)$ scale. A) Cochran's Q is plotted against Rucker's Q for each SNP, as calculated in a leave-one-out analysis. Outliers have been visually identified and are labeled. Q-statistics for the model with the full set of 64 SNPs (red) and with outliers removed ( 61 SNPs, blue) are shown. B) SNP effect on yearly hospital admission count is plotted against the SNP effect on BMI. Fitted lines are displayed for the random effects MR-Egger, penalized weighted median, weighted mode and random effects exact weight IVW models. The outliers identified in plot $A$ are shown in blue. * denotes a significant slope.

## WHR

A

B

Figure S2. Plots for two-sample MR analysis of WHR effect (per SD, with SDwHR=0.07) on yearly hospital admission count in UK Biobank participants of White British ancestry. Effects are shown on the $\log (r a t e)$ scale. A) Cochran's $Q$ is plotted against Rucker's Q for each SNP, as calculated in a leave-one-out analysis. Outliers have been visually identified and are labeled. Q-statistics for the model with the full sets of 34 SNPs (red) and with outliers removed ( 30 SNPs, blue) are shown. B) SNP effect on yearly hospital admission count is plotted against the SNP effect on WHR. Fitted lines are displayed for the random effects MR-Egger, penalized weighted median, weighted mode and random effects exact weight IVW models. The outliers identified in plot $A$ are shown in blue. * denotes a significant slope.

## WHRadjBMI

A

B

Figure S3. Plots for two-sample MR analysis of WHRadjBMI effect (per SD, with SDwHR=0.07) on yearly hospital admission count in UK Biobank participants of White British ancestry. Effects are shown on the $\log (r a t e)$ scale. A) Cochran's $Q$ is plotted against Rucker's $Q$ for each SNP, as calculated in a leave-one-out analysis. Outliers have been visually identified and are labeled. Qstatistics for the model with the full set of 45 SNPs (red) and with outliers removed ( 41 SNPs, blue) are shown. B) SNP effect on yearly hospital admission count is plotted against the SNP effect on WHRadjBMI. Fitted lines are displayed for the random effects MR-Egger, penalized weighted median, weighted mode and random effects exact weight IVW models. The outliers identified in plot $A$ are shown in blue. ${ }^{*}$ denotes a significant slope.
